THE

MEDICAL TIMES:

A JOURNAL

OF

ENGLISH AND FOREIGN MEDICINE;

AND

MISCELLANY OF MEDICAL AFFAIRS.

VOLUME THE SEVENTH.

SEPTEMBER 30, 1842, TO APRIL 1, 1843.

LONDON:

J. ANGERSTEIN CARFRAE, 49, ESSEX STREET, STRAND.

M.DCCC.XLIII.

PREFACE.

In the management of this Journal, and especially during the last six months, if we have laboured under any one governing and paramount wish, or felt any one inclination with that over-anxiety which predisposes the most right-minded man to partiality or prejudice, it was the wish and inclination, fairly, to help our *successful* medical brethren to retain their elevation, and to assist those struggling for scientific notice in their deserving efforts after greater altitude. In the whole circle of the Profession we wished no medical brother ill whose conduct allowed justice to wish him well. We knew that our Profession gave, at the best, not too much happiness to its members, and, where duty would allow, we wished not to mark out from among them victims, for the misery ever caused by distempered invective and poisoned sarcasm. We felt that our Profession was not too united or harmonious; and we would avoid the needless task of kindling fresh coals of strife. We were convinced that society had not too high a notion of our claims on their regard and respect; and we could think it no duty of ours to lend them, with the *Lancet's* certificate, our authority for their injurious estimation. With these convictions, a consideration of interest operated with scarcely less potency. The wanton and unprincipled personalities of the persons who preceded us in the care of this Journal, made it essential, as a point of policy, that we should be overmeek to prove our fairness, and run into the very verge of fastidious prudery to satisfy the world of our claims to common honesty. Interest and duty thus conspiring to make us the favourable censor of our brethren—nothing, it may be easily conceived, but a paramount sense of justice could ever prevail on us to deal with any one of them in a harsh, or severe, or retributory spirit. It was with real pain, therefore, that we found ourselves in collision with the Physician whom we have designated, we think not untruly, the Ishmael of our Profession. We wish not to dwell on the transaction. Every one must be convinced that Dr. Hall treated us in it with an ill usage only second to that with which he has been accustomed to treat himself; and we own, that if we can survey it without reproach, we cannot without pain. Though we felt bound to expose the breach of faith we suffered from, and mark with an ineffacable brand the innate, incurable, monomaniacal dishonourableness in which it originated, our justice went no further; and the very man who causelessly provoked our anger, feels grateful for the moderation which marked its display. As we sought not the affray then, we would sing over it no triumph now; and it will be no fault of ours if its beginning, middle, and end, lie not for ever entombed in the volume which we now close.

Casting this unpleasant reminiscence aside, we think we may look back with some pride to the exertions we have made during the last six months in purveying for our readers amusement and instruction. The lectures alone which we have placed before them have fairly been worth more than the whole expense our subscribers have had to pay for the volume. Few things of worth have been presented in any British or Foreign Medical Periodical, however costly, which have not been made known to them. The original articles we have submitted to them have not wanted the highest scientific interest. The communications of Dr. Clay, on his daring and successful operations for Diseased Ovaria, may be cited as among the most valuable contributions that have been made through any Journal, of late years, to Practical Surgery. The unanimous voice of the Profession has acknowledged our Pencillings to deserve inscription among the happiest efforts of biographical literature; they sparkle at once with the highest moral and mental qualities; and, with reference to our own efforts, editorially, it will not be denied that our emphatic condemnation of abuses on the one hand, and our earnest advocacy of improvements on the other, have never been wanting when there was any just cause for either.

We shall perhaps be the more excused for supposing some little desert on our side in all this, inasmuch as it will explain, flatteringly, to the public taste—which we would think well of—the prodigious success which has crowned our exertions. With the expansion of our labours have expanded, in even disproportionate largeness, the numbers of our supporters. We are now incontestibly at the head of British Medical Periodicals, in reference both to influence and circulation; and, if history may serve as the ground-work of prophecy, we are justified in anticipating, and for no distant day, an extension unparalleled in the annals of class publications. The proportions of the Medical Times are already those of a giant, but of a giant who has not yet reached his full growth. 'Tis Hercules emerging from his cradle. The explanation lies in the fact, that while other Medical Journals have been but the dirty instruments of an ambitious or notoriety-hunting individual, or the puffing circulars of interested book publishers, the Medical Times is felt to be the emanation of the Profession—directed by minds which feel and represent their aggregate interests—its one sole absorbing mission, their good. This independence and representative faithfulness is the secret of our success—the essence of our power, a power which, as it has never been more needed by the Profession, will be applied to the protection of their interests with an energy proportionate to the force of that fulcrum on which all our efficacy rests—their support.

With these few prefatory words, we usher into the world another volume. Another telling memento of Time's fugitive course, it seems as though formed in a handful of days, a period short in retrospection, as the passage through the brain of the thought it raises—brief period, so few of which measure the sum of man's activity! How forcibly does the thought justify Hippocrates' contrast for us of the duration of art with the brevity of life! The lightest minded might be pardoned for turning moralist before a consideration which fails of its natural effect if it stimulate not to renewed diligence in the labours of utility and benevolence—if it elevate not above too warm an interest in the more sordid strifes of the passing day, which are only of engrossing importance because seen but in the deceptive microscope of the Passions—if it fill not with an inspiring consciousness that the only pains truly worthy of us are those which spread beyond, and last behind us.

INDEX TO VOL. VII.

THE MEDICAL TIMES

A Journal of English and Foreign Medicine and Medical Affairs.

No. 159. Vol. VII. LONDON, SATURDAY, OCTOBER 8, 1842. PRICE FOURPENCE. Stamped Edition, 5d.

For the convenience of Subscribers in remote places, the Weekly Numbers are re-issued in Monthly Parts, stitched in a Wrapper, and forwarded with the Magazines. Orders for the Stamped Edition (10s. 10d. per Half-year, Post-free in advance,) are received by any Bookseller or Newsman, or may be directed to J. A. Carfrae, Esq., at the Medical Times Office, [illegible] London.

SUMMARY.

ON THE LAWS OF THE DEVELOPMENT OF ORGANS; OR TRANSCENDENTAL ANATOMY APPLIED TO PHYSIOLOGY.

By E. R. A. SERRES, Member of the Institute, of the Academy of Medicine, Professor to the Museum of Natural History, Paris, &c., &c., &c.

Summary—Return of modern physiologists to the theory of epigenesis—Causes of this return—Necessity of combining the examination of the views of the ancients with those of the moderns in pursuing the theories of organogeny—Consequences and deductions of these theories—Relations which organogeny establishes between the invertebrata and the vertebrata—Application of its principles to pathological anatomy as well as to vegetable life—Aristotle, the proposer of the theory of centrifugal development—His botanical and zoological classifications founded on physiology—Galen; his comparison of the formation of animals to the construction of a ship, adopted by Fabricius d'Aquapendente—Further views of the latter—Harvey, the first founder of the theory of Epigenesis; formation of the embryo by the addition of parts, by super-position, juxtaposition, adhesion, &c.; his views on ovology.

We shall now endeavour, as clearly as possible, to define this science, by briefly tracing the history of the development of man and of animals. We will explain the principles of this development, as well as its laws, and its relations with the other natural sciences. Interesting in its nature and object, this study acquires, from the labours and notions of the age, a still greater value. The system of *pre-existence of organisms*, till lately so universally adopted, has completely fallen to the ground, and the theory of epigenesis, so long abandoned, but so perfectly in accordance with the spirit of the age, has again risen in its place. "Once more," to use the prophetic expression of Lord Bacon, "has truth triumphed over error." This advance of organogeny is due to improved observation and philosophical deduction. In the deficiency or uncertainty of facts, the mind seeks to supply their place by hypotheses; but in proportion as facts multiply—in proportion as they are elucidated by perseverance and observation—so are the reasoning powers enabled, by a comparison of their relations, to separate the true from the false materials. Hence results the necessity of combining the examination of ancient with modern opinions. Often, indeed, the truth becomes incomprehensible, unless we previously familiarize ourselves with the hypothetical conclusions which have been drawn.

Such is especially the case with organogeny, inasmuch as it serves as the basis to the theory of the centripetal development of man and animals, in contra-distinction to the hypothetical theory of centrifugal development. For, if the *organisms* of man and animals are formed from the circumference towards the centre: if the centripetal law is the general and common rule of all organic developments, it becomes essentially necessary to ascertain how the centrifugal law was established in opposition to it; what were its bases, and what its proofs. If, as according to the doctrine of epigenesis, the *organisms* are originally divided or seperated into distinct portions, ought we not to ascertain whence arose the centrifugal law, that last remnant of the doctrine of pre-existence, which supposes these *organisms* to be formed entire and without division? According to the former theory, which is entirely borne out by observation, we may trace the gradual and successive development of the *organisms*, their passage from one state to another totally different, their various transformations or metamorphoses &c.; while the advocates of pre-existence assert that all organization is in reality immutable, that the whole development consists in a transition from small to great; so that the fœtus is but a repetition of the perfect animal, the embryo of the fœtus, and the ovum and even the ovule, an infinitely minute repetition of the embryo; thus supposing the entire animal to be contained in a perfect state in the generative organs, and as it were enclosed the one within the other since the formation of the world. The solution of this question becomes of immense importance as well in a physiological as an anatomical point of view. For if the *organisms* of beings existed in a perfect state in their ancestors, even of the most remote degree, as the advocates of pre-existence assert, we perceive the whole force of the argument respecting hereditary predisposition in races. If, on the contrary, the parents furnish to the being, but the elements of the body which is afterwards evolved within itself, by a series of successive transformations, up to that definitive condition in which it appears in the world, then human liberty and individual responsibility resume their right.

The doctrine of epigenesis is moreover in accordance with the facts discovered by experience. But still we require a principle which, without distorting, will bind these facts together. Accumulated as they are, without limit, without rule, without locality, they make of general and comparative anatomy a perfectly dead science likely only to dishearten and disgust the mind by the aridity of its conceptions, or else mislead by dragging it into the labyrinth of German metaphysics. But freed from these pre-conceived views which were destined to connect it with another order of ideas, organogeny presents to us nature in its true grandeur. The earth is an immense laboratory in which there is constantly developed, since the first appearance of life upon the globe, a succession of new beings whose organization, following a progressive and ascending scale, gradually mounts from the infusoria, the lowest point of animal life, up to the mammifera and man, the highest of nature's efforts. Science thus exhibits a constantly ascending scale of life, guarded, at various distances, by wider lines of demarcation, periods of rest as it were; so that the whole animal kingdom appears to be in some measure but as a single animal which, during the formation of its various *organisms*, becomes arrested in its development, earlier in one part, later in another, and which thus determines at each period of its interruptions the distinctive and organic characters of classes, families, genera and species.

Hence comparative embryogeny, regarded useless and without object according to the theory of pre-existence, resumes among the physiological sciences the elevated rank assigned to it. In this point of view, in fact, we see embryos of the superior animals temporarily clothed with the organic and permanent attributes of the lower animals; while the permanent *organism* of these latter delineates in its successive degrees of perfection, all the embryonic phases of that scale of beings most approached to the lowest vertebrata. We thus bring within the sphere of general and comparative anatomy the immense collection of invertebrated beings, which, for want of a better classification, are at present but a source of confusion and error to science. What is there, in fact, similar between the *organisms* of the annelida, of the mollusca, and that of the vertebrata, if considered when the latter is arrived at the last stage of development? What is the law which could embrace within its scope *organisms* so different, so distant, and whose contrasts are so striking to the eyes of the inexperienced observer? But when we elevate in idea the *organisms* of the invertebrata, or, which comes to the same point, lower in a like proportion the *organisms* of vertebrated animals, we shall obtain comparable elements, and shall be enabled clearly to distinguish their differences as well as their analogies. This is precisely what nature does in the grand scale of organogeny. Not being able in the actual order of its developments to raise the invertebrata, it brings the vertebrata to their level. This is the remarkable feature which embryogeny presents in these latter animals. Follow in all their phases the multiplied changes which their *organisms* undergo during development; dwell on each of their metamorphoses; study with care their characters, and you will see these transformations delineated, each passing through the forms and attributes of the permanent organization of invertebrated animals.

Such is the general result of embryogeny. One by one its most essential consequences become unfolded. In the first place, if comparative anatomy is a species of permanent embryogeny, organogeny is, in its turn, a transitory kind of comparative anatomy. Secondly, if *organisms* in the course of their development become arrested in their progress, they must necessarily reproduce those of some animal of a lower rank in the scale of existence. 3rdly. Pathological anatomy, or that relating to abnormal organizations, is in reality but organogeny in an arrested stage, or, what amounts to the same thing, it is but a new form of comparative anatomy. 4thly. If the *organisms* of the lower class of beings are but those of the superior class in the course of development, we necessarily have a new impulse given to organogeny by the study of vegetable life. Lastly, and this point is of importance—if the formation of organised beings may be reduced to certain rules, these organogenic rules will consequently be applicable, both to comparative and pathological anatomy, perhaps even to the system of vegetable life; for in science, as in nature, everything seems connected, and intimately bound together.

We thus see that the primary or fundamental question of organogeny and of zoogeny, is reduced to this: whether the *organisms* of animals become gradually formed, or whether they pre-exist.—These two opposite opinions have, since the origin of science, been contested under the names of epigenesis and of pre-existence. During the last century, the doctrine of pre-existence prevailed from considerations unconnected with anatomy and physiology, and epigenesis was rejected from a too early despair of discovering the laws presiding over the formation of *organisms*. The law of centrifugal development is the consequence of the theory of organic pre-existence, as the centripetal law is the consequence of epigenesis. The general question thus merges in the discussion of these two laws; and we shall, while seeking the supposititious origin of the first, see delineated the facts which establish the second.

Aristotle must be in some measure regarded as the founder of the theory of centrifugal development. His extensive mind, embracing within its grasp all organised beings, and foreseeing the necessity of a mode of distinction, arranged them under that classification common to all, named *life*. Starting from this point, he divided organized beings into two classes: those which, like vegetables, have but a single mode of existence, vegetative life, and those which, like animals, have, besides

vegetative life, that of *relation*. This first classification of zoology and of botany, was consequently entirely physiological. This admitted, Aristotle established that the appearance of vegetative life upon the globe must have preceded animal life, which, he states, was merely superadded to the former with a view of perfecting organised beings. Animals being endowed with two kinds of life, the development of each, as well as that of the corresponding organs, must be subjected, he adds, to the general law of vital manifestation; for animals are but moving vegetables endowed with free communication one with another. The question of organogeny is thus reduced to a simple topography of the vegetative apparatus and of those of *relation*. Now, who is unacquainted with the fact, that the heart, and the lungs, the stomach, and the intestines, are placed in the centre of the perfect animal; whilst the organs of the senses, and those of locomotion, occupy its outer portion? According to the principle of Aristotle, development should then proceed from the centre towards the circumference, or from within outwards. The senses indicate it, says this great naturalist, and reason cannot conceive otherwise. To judge fairly of this theory, which afterwards became so celebrated, we must carry ourselves back to the precise period where Aristotle makes the development of animals to commence. This was neither with the vesicle of de Graaff, which was unknown to him, nor with the ovule, of whose existence he was likewise ignorant, nor even with the membranes of the ovum, nor the little *cicatricula* or rudiment of the embryo, of which in his time no precise notions were entertained. According to him, the first development of the ovum and of the embryo-germ are not animal formations. These developments belong to vegetative life. The animal, according to Aristotle, does not commence until the movements of the heart manifest themselves. Then only it becomes a moving being (*per se movens*), it ceases to be a vegetable, and is endowed with the first characters of animal life. The appearance of the movements of the heart was then, according to Aristotle, the commencement of embryogeny; and this organ became the centre whence all others radiated towards the circumference. This erroneous view was the first source of the theory of centrifugal development.

Without stopping to consider the objections which even the order of developments furnishes against this opinion, we ask of modern physiologists, who among them would venture to assume the responsibility of propagating such a notion? Who would dare to maintain that the ovule and its membranes, that the ovum, its coverings, and the first traces of the embryo belong to the vegetable kingdom? Who would make animality to commence with the tardy appearance of the heart, whether in the embryo, or even in the animal kingdom, and thus throw back among vegetables, the infusoria, the zoophytes, the greater part of the annelida, and even some of the mollusca? Still it is upon this rash ground that the hypothesis of centrifrugal development is henceforth to rest. Every being destitute of a heart is to be arbitrarily excluded from the animal kingdom.

Galen, whose treatise, *de usu partium*, deservedly ranks so high, adopted without restriction the views of Aristotle. Not having traced, like him, the different phases of formation in the chicken, he was unable to maintain his opinion as to the undoubted evidence of the senses; but he made amends by calling to his aid all possible forms of reasoning. His comparison of the construction of a ship, of which he made use to render the conception of developments within the reach of every body, has been extolled down to the present day. Now, says Galen, in this construction, the builder first lays down the keel, which constitutes the centre of the vessel; in the same way nature first forms the centre of the animal, which, for this reason, has by some been named the *carina*; then, around this centre, the lateral parts of the animal, as in the ship, become successively placed or supported, so that, in both instances, the formation takes place from the centre towards the circumference; for nature is the image of art, or rather art in this case but imitates the work of nature. This comparison appeared unanswerable to the host of followers and admirers of this physiologist, and the building of a ship became without opposition in all the schools the emblem of man's development, which Galen declared with reason to be the grandest of Nature's operations. We must here remember the immense influence which this physician for a long time exercised over the minds of anatomists, to be enabled to understand the prodigious success of this manner of interpreting the mystery of organic developments.

Aquapendente even sacrificed to it his own views. This remarkable man, who among ancient physiologists best comprehended the problem of the formation of animals, traced with a bold hand the course which could alone conduct to its solution. The chicken, said he, is preceded by the egg: to understand how the first is developed, it is, therefore indispensable, he concludes, to trace the formation of the second. This rigorous and strictly logical method led him to the discovery of the ovigenous vesicle, to which De Graaff afterwards attached his name, and the use of which it was reserved to Malpighi to unfold to us. From this vesicle, Aquapendente traced the ovum, which is one of its products. The ovum thus formed or secreted by the ovigenous vesicle, he followed step by step its transformations in the course of incubation. Directing his attention especially to the development of the membranes, he observed that these formations precede the development of the *cicatricula*, in the middle of which appear the first traces of the chicken. Then applying himself to the formation of the latter, he came to the conclusion that the chicken is formed at the expense of the ligaments of the yolk, of which it seems but a prolongation: an ingenious idea which was subsequently applied by M. Oken to the mammifera. Following up this reasoning, Aquapendente believed that he had discovered in the three primary protuberances of these ligaments, the origin of the three large cavities of the upper class of vertebrated animals: the head, the thorax and the abdomen; and that the limbs were merely superadded at a later period to these three principal centres of life. Now, the ligaments are situated at the extremity of the two diameters of the egg; in unfolding themselves they advance from without inwards; their progress is then concentrical; and if these ligaments form the chicken, it is manifest that the constituent materials of the animal are directed from the two extremities of the egg, to the central or median point where the *cicatricula* manifests itself. Thus nature, in this work, obeys the centripetal law. This conclusion is inevitable, and everything indicates it to have been the idea of this anatomist, although he does not positively express it in his writings.

If Aquapendente had been unbiassed by preconceived notions; if he had followed the bent of his own observations, as evidenced in his able researches on incubation, there is no doubt but that he would have laid the foundation of centripetal developement; but making the commencement of animal life to depend, according to the views of Aristotle, on the appearance of the heart, he was led still further astray than Galen in his views on this subject. The comparison of the construction of a ship appeared to him so ingenious that he was constantly quoting it. He went still further; for he asserts that, as the artist first lays down the most solid materials to serve as a foundation for the others,—so, in the formation of animals, nature commences by the development of the bones, and then constructs around this solid frame-work the other organic tissues. What! the bones precede all other organs! Well may Harvey demand, if it was really Aquapendente who made this surprising assertion. Who, in fact, does not know that, in the order of organic formations, the bones—the solid part—are the last to manifest themselves?

Harvey, tracing in his turn incubation and the first stages of generation with that eagle-eye characteristic of his genius, cast on all sides flashes of light which struggled to dissipate the ancient doctrine; his mind, strengthened by observation, could not conceive these formations to be only a modification of organic matter which should merely change in form, at the various periods of development, as clay under the hands of the potter. He could not see the embryo in the ligaments of the yolk, and the entire chicken in the *cicatricula*. "It is there," he adds, "or it is not there. If it is there, who can show it; and if it is not there, if no one can discover it, why suppose that it is? Is this the manner in which we should proceed in this difficult branch of science? Is not the study of existence already sufficiently complicated? Must we add to it the solution of our dreams, and the contradiction of our suppositions?" Harvey could not conceive the embryo to undergo a series of transformations only, according to the idea of Aquapendente, and as the disciples of the theory of pre-existence more recently supposed. The embryo, of which the first rudiments are in the *cicatricula*, is formed by the addition of parts, by super-position, juxta-position, cohesion; whence it follows, that the whole being is not contained in the primitive nucleus, but results from a succession and association of the various parts. This new language gives for the first time a scientific character to the doctrine of epigenesis. But unfortunately Harvey, like his predecessors, attributed to embryogeny two kinds of life, for he states that the membranes of the ovum, the first outline of the embryo, are the product of a peculiar life. Up to this point the organized being is a vegetable, it is only animalized with the first pulsations of the heart, which this physiologist in like manner makes the *primum vivens*. From this consideration, commencing only at this point of organogenic study, Harvey believed, and was, as it were, bound to believe in the reality of the centrifugal development of Aristotle. This was his error, but this error was compensated by discoveries and by new views, which are almost worthy of ranking with the immortal discovery of the circulation.

"All animals and man," said he, "proceed from an ovum;" and since the time of Harvey the most profound anatomical researches—the most minute microscopic observations—have revealed to observers that the ovum is, in fact, the general *matrix* of the animal kingdom. In creating ovology, this bold idea at the same time opened new routes to embryogeny and zoogeny. If, indeed, all animals proceed from an ovum, do we not perceive in that general fact the germ of the primitive analogy of animals which our illustrious Geoffroy Saint Hilaire traces through all *organisms*? Do we not also see that all animals must arise from this common ovum, according to constant order and invariable rule—as Harvey positively asserts? May we not also, finally, perceive that, to discover this order of formation, it is indispensable to follow attentively the gradual and successive appearance of the *organisms*, a course which this great man laid down as a general precept? The consequence, so to speak, of this manner of studying organogeny, is a conviction that the embryos of the superior animals and of man must traverse in their development the organic states which characterize the lower class of animals: a truth, the demonstration of which will, perhaps, constitute one of the glories of our age.

In all the animal kingdom the first product of generation is a simple being, almost identical throughout the whole series. It is an ovum, that is to say, a fluid surrounded by a membrane, to which is added a small zoosperm. The ovum is furnished by the female, the zoosperm by the male. We find both the one and the other, and each apart, in the generative organs of the sexes whether these organs are combined in the same animal, or whether they belong to separate individuals. Thus we have in a distinct state the two elements, differing in nature, the combination of which gives birth to a new being. But how does this combination take place? What passes within the ovum and the zoosperm at the moment when the union of these two elements is accomplished? This mystery seems impenetrable to our senses; God only knows the secret. We may indeed perceive some differences between the fecundated and the unfecundated ovum; but these differences however important in themselves, are altogether trivial when compared with the great act which has taken place, with the grand result produced by incubation and development. There is, however, a chemical phenomenon which seems to have some analogy with the generative process, that is the formation

of salts. As in generation, there are here two distinct principles, the salifiable base and the acid; so, also, there is a new product, a binary compound, the salt. Now we may compare the salifiable base to the ovum, the acid to the zoosperm, and the salt to the fecundated ovum. But what passes at the moment of penetration of the base and of the acid? How is it that a salt is formed with properties so different from its two *radicals* when taken separately? Of this we are ignorant. Neither the theory of equivalents nor that of substitutions can explain it. Electricity also leaves us in the dark. If this natural and simple phenomenon is a mystery to the chemist, can we be astonished that the physiologist should be confounded by the infinitely more elevated phenomenon of generation? The chemist, indeed, performing himself the mixture, the generation of the salt, which takes place under his eyes, seems an experiment of a more certain character than that of generation, for with the two *radicals* he can create the salt at will. But this degree of certitude, if such it be, the physiologist has, in common with him, for the physiologist can place in one vessel the *non*-fecundated ova, and in another the zoosperms. By pouring the latter over the ova, he can create animalcula at will, in the same manner as the chemist forms salts; and this generation may be performed not only on the infusoria, the mollusca, the annelida, the crustacea, and on insects, but even fishes and reptiles, advanced as they are in the scale of organization, may be developed in this manner.

PRIVATE COURSE OF OPERATIVE SURGERY.

By J. NOTTINGHAM, Esq., Member of the Royal College of Surgeons of London.

INTRODUCTORY LECTURE.

Prefatory Remark.—Rarity of Good Operative Surgeons.—Difficulties surrounding this Branch of Science.—Professor Jungken's Opinion.—Opinion of Celsus on the Qualities required.—Utility of Anatomical Investigations, and Vivisections.—Improvements in the Law in this respect.—The Uses and Advantages of Ambidexterity.—Of an acquaintance with the Dead and Foreign Living Languages.—Of enlarging the Powers of the Mind by extended Studies.—Especial Need of a Knowledge of the various Divisions of Medicine and Surgery.—Professor Serres, Lectures.—The great art, the safely avoiding Operations.—Closing Remarks.

Gentlemen,—In commencing a course of lectures on any scientific subject, or on any department of art,—it is customary to give at least a few preliminary notices of the history of the science, we are about to treat of; and this is generally done by the professors or teachers of Medicine and surgery. As the course of lectures, however, which we now commence will be confined, as much as possible, to operative surgery, without attending to any of the details which relate to what may be called the medical section of this branch of the healing art,—we may be allowed to dispense with the historical preface, which, if short, would, of necessity, be very imperfect and unsatisfactory; and if long, or at all approaching perfection, would occupy the greater part of that time, which we propose to devote, to an account of the present state of operative surgery. Besides which, it is of the utmost importance, that we should consider well and make ourselves acquainted with surgery as it is,—while a knowledge of the details of its early history, amongst the various cultivated and polished nations of antiquity, although an interesting part of the luxury of erudition, is not an indispensable attainment for a good surgeon. We may, however, remark on the close of these observations that the modern, but more especially, the recent history of surgery, should be methodically stored in the memory of every one of us, if we desire to do justice to those, who, from time to time, within the last two centuries more particularly, have aided by the influence of their genius, or the unwearied application of their industry, the late progress of this noble pursuit.

Every one who has attended to the history of the healing art, must have been struck with the obviously small number of men, who have been distinguished as operating surgeons; for how many rare qualifications are required, and how great are the difficulties in the way of attaining them; for if we may believe the statements of surgical writers, it is only a very small proportion of those, who even diligently study our profession, who arrive at any considerable distinction as operating surgeons. Some branches especially of operative surgery, present greater difficulties than others; for instance, on the one hand, that class of operations called great or capital, such as the more important amputations, the operations for stone, the ligature of great and deeply seated blood-vessels, the removal of certain tumours, the operations for strangulated hernia, requiring for their speedy, safe, and effectual performance, the most exact anatomical knowledge joined with an adroitness of surgical manipulation, and the enjoyment of an imperturbable coolness; on the other hand, that class of operations, sometimes called minute, in which the organs of sense are frequently concerned, and of which, operations on the eye, afford a convenient illustration; for here, a knowledge of the minute anatomy of these delicate organs, must be brought to the guidance of the scissors, the probe, the cataract knife, or the couching needle; all delicate instruments, which become dangerous weapons in the hands of the ill educated surgeon.

The German Professor Jüngken, in his work on the operative surgery of the eye, remarks, that although he had taught during ten years this branch of surgery to a half yearly class of about thirty students, very few of them attained to such perfection in the art, as to enable them to perform these operations tolerably well on the eye of the living subject.

Since the excellent regulations of the Apothecaries' Hall of London, have obliged medical students to read a little more of the Roman tongue, the qualifications of a surgeon as laid down by Celsus, have become tolerably familiar to us. The Latin writer, says:—

> A surgeon ought to be young, or at most, but middle aged, to have a strong and steady hand, never subject to tremble, and to be no less dexterous with his left than his right hand; to have a quick and clear sight; to be bold, and so far void of pity, that he may have only in view the cure of him whom he has taken in hand, and not in compassion to his cries either make more haste than the case requires, or cut less than is necessary; but do all, as if he were not moved by the shrieks of his patient.

The truth of such remarks will not, indeed, be doubted, and this list of the personal qualifications of the surgeon, has been repeated and commented on by most succeeding writers on the subject, who have not, however, given sufficient attention to those occupations, studies, or modes of education, which assist us in attaining to the conditions here traced out.

It is fortunate that the study of anatomy and physiology oblige us to betake ourselves to the very occupations, which tend so efficiently to prepare us for the practise of operative surgery; for the constant handling of the scalpel, the forceps, and other instruments, which dissecting-room pursuits require, gradually imparts to us that adroitness in manipulating these instruments which tells so well when we have similar ones to apply to the living body; while those operations on the lower animals during life, which are indispensable to the scientific physiologist, accustom us to the screams, the writhings, and violent efforts, which to the surgeon not well initiated, are not only painful, disagreeable, and troublesome, but now and then oppose effectual barriers to the completion of that which might otherwise have been a tolerably good operation; this is often seen more especially to interfere with the surgical treatment of children.

We may congratulate ourselves that the well educated portion of the community, now no longer display those insane prejudices which for so many centuries kept back the progress of anatomy and physiology, and wilfully and resolutely kept in the dark, all the beauties displayed by the structure, and the miraculous workings seen in the functions of living and organised bodies. We no longer complain of the strange contradiction in our institutions, which permitted the co-existence of chartered bodies to examine men in anatomy, and of laws to prevent its study; happily, we begin to tread on the heels of our friends across the channel, in all that relates to good regulations for the furthering of these departments of science, as they do upon ours in many sections of public improvement, mechanical science, and productive industry. Nor are those departments of experimental physiology, any longer regarded as monstrous and cruel, which oblige the scientific inquirer occasionally to inflict pain on those creatures, whose organs more or less resembling corresponding parts of the human economy, have been interrogated with the aid of the knife, and thus compelled to declare the secrets of their structure, and actions, in this way throwing a light on the admirable mechanism of man which could not be studied in a similar manner.

Indeed, while such prejudices did exist, it was often more amusing than painful, to listen to the manner in which they were expressed, for those who were loudest in their declamations against the inquiries in question, which might be said to produce food for the mind, were seldom found commenting on those sufferings of the lower animals, the results of which are food for the belly; to fry certain kinds of fish alive, or to produce blanched veal by repeated venesections, or to imprison many of the brute creation, and confine them during weeks or months, to an artificial and fattening diet, were not discovered by the same possessors of refined feeling to be in any way either torturing or shocking. We will, however, leave these matters as they are, to the future improvement and progress of which they are capable, satisfied with the pleasing encouragement, which the present state of civilisation, gives to every branch of rational and fair enquiry, and to the prosecution of every useful art.

It must be remembered then that these habits of dissection, and occasional vivisection, are of such importance in the training of the nervous system and of the hand of the surgeon, that however much some weak-minded people pretending to gentle manners, and tender heartedness, should attempt to speak against them, their eloquence is to be treated as sounding brass, or the tinkling cymbal, and they are not to be listened to, even if they quoted the pathetic lines of the poet—

> I would not enter on my list of friends, &c.

Few surgeons are ambidexterous, yet all may become so; Celsus, and those writers since his time, who have copied, or imitated him, attach considerable importance to this acquisition which is capable of warding off a great deal of inconvenience, and preventing

as much disagreeable awkwardness. It is not easy beforehand to divine what men morally, intellectually, or manually, are capable of, and we ought to consider, that there is every incentive to the adoption of methodic and persevering culture, for the purpose of overcoming those difficulties before alluded to, which have been said to be so great, and which are believed to be capable of limiting so much the number of good practical surgeons; indeed the very difficulties themselves have within them the germ of our greatest and best reward, for in proportion to their magnitude, will those who overcome them be few, while the less the number of labourers, so, at the same rate, greater and more promising will remain to each the products of the cultivated field.

Hence, it is evident, that the surgeon is of all others, the man who most should study himself, should discover his own weaknesses, and endeavour to remove them, while he finds out at the same time the sources of strength with which they are associated, and determines wisely to apply them.

The pursuits and operations above noticed, will declare to him something of his own capabilities; and will unveil the nervous feelings or weaknesses he may have to overcome; the source, the nature, and course of which, being scrutinized and understood, he will, instead of despairing of success, be ready to exclaim with the Roman poet —

Felix, qui potuit rerum cognoscere causas;
Atque metus omnes et inexorabile fatum
Subjecit pedibus, strepitumque Acherontis Avari!

But when these characteristics of the quality we call firmness, are possessed in the fullest extent, the surgical student must still regard himself as merely standing on the threshold of preparation, beyond which its innermost chambers, and farther *Arcana* have yet to be seen, and which will be found to contain much that is associated with higher moral and intellectual advancement, and with acquisitions not so easily made.

Here we may be allowed to remark, that as the study of medicine and surgery, are generally commenced at so early a period of life, that it would be impossible for an extended classical and mathematical, or a literary and scientific education already to have been attained; the surgical student should be strongly recommended, to add a little every day, to the schoolboy's former attainments; if he neglect to do this, and devote himself exclusively to his professional studies, he will find when it is too late that he has badly economized his intellect, and his industry, in losing sight of some of the sources of the greatest profit as well as enjoyment. That period of time which is in this country occupied by the preliminary studies or by the apprenticeship, is of inestimable value, if rightly used, for it affords ample opportunity, not only of keeping up and improving the attainment already alluded to, but of acquiring such knowledge of modern languages, particularly French and German, as will afford no trifling aid in our future surgical studies; nor will this be the only source of their importance and value, for a moderate knowledge of the literature and science of our neighbours, will tend to correct that common narrow mindedness, which attaches a superior value to everything belonging to ourselves. In support of such sentiment let us quote the language of one countryman who to a [illegible] of professional attainments join a [illegible] and [illegible] who not only [illegible] the [illegible] of the German [illegible] when such acquisition in this country was much less common than at present, but generously [illegible] to the world, the best results of his labours in his valuable and classical writings. He says,—

"The temple of science has not been raised to its present commanding height, or decorated with its beautiful proportions and embellishments, by the exertions of any one country. If we obstinately shut our eyes to all that other nations have contributed we shall survey only a few columns of the majestic fabric, and never rise to an adequate conception of the grandeur and beauty of the whole. Our insular situation, by restricting intercourse, has contributed to generate a contempt for foreigners, and an unreasonable notion of our own importance, which is often ludicrous, always to be regretted, and, in many cases, strong enough to resist all the weapons of reason and ridicule. We should consider what we think of these national prejudices, when we observe them in others; when we see the Turks summing up all their contempt for their more polished neighbours, in the short but expressive phrase of "*Christian dogs*," and the Emperor of China accepting presents from the King of England, because it is a principle of the Celestial Empire to shew indulgence and condescension towards *petty states*.

Science requires an expanded mind—a view that embraces the universe. Instead of shutting himself up in an island, and abusing all the rest of mankind, the philosopher should make the world his country, and should trample beneath his feet those prejudices which the vulgar so fondly hug to their bosoms. He should sweep away from his mind the dust and cobwebs of national partiality and enmity, which darken and distort the perceptions, and fetter the operations of intellect. If the love of science and liberal views are not sufficient to repress the noisy obtrusion of national claims, considerations of policy may furnish the motive. The country which has really done the most for science, will certainly be the last to assert its pretensions; and a readiness to allow the merits of others will be the most powerful means, next to modesty and diffidence, of recommending our own to attention."

It is, however, very easy to fall into this habit of national partiality, or rather it is difficult to avoid it: Richerand when speaking of the English, says—that "they are too proud of their Bacon, their Locke, and their Newton, and vainly aspire to a superiority too universal;" yet he immediately after, is disposed to persuade us that J. L. Petit was superior to Cheselden, and that John Hunter cannot be compared with Desault. If we could suppose that scientific men were influenced by current popular prejudices, or tinctured with the lasting animosity resulting from the events of war, we might be disposed to regard Richerand as somewhat biassed in this way for the date of his writing was such, that the bones of Waterloo scarce whitened the plain, which as yet was steeped with blood.

Without multiplying these remarks, let us remember the expression of Burke that "he who calls in the aid of an equal understanding, doubles his own; and he who profits of a superior understanding, raises his powers to a level with the height of the superior understanding he unites with," for it suggests the policy of doing justice to our neighbours, and taking right advantage of their labours at the same time.

As we have preferred the discussion of the duties and necessary attainments of the surgeon to the early history of our art for the greater part of this discourse, we may, for a moment, direct our attention to observations which have been made on such subjects, and which deserve to be treasured in your memory.

The well known French writer, Martinet author of the valuable little work on Pathology, when speaking of the qualification of the Medical Observer, says "Whoever wishes to extend the boundaries of science, should commence his education, by acquiring a perfect knowledge of the Greek and Latin languages and should then proceed to learn the modern languages, particularly the French, Italian and German. This is necessary to enable him to study with effect the many excellent works, published by our neighbours; and (should he visit those countries) to observe with advantage their clinical practice, and form an accurate estimate of their modes and principles of treatment.

The Observer should acquire correct ideas of several sciences which may be deemed accessary to medicine. He should be acquainted with Chemistry, Natural History, and Natural Philosophy, as he will constantly have occasion to make application of their principles; and if he be ignorant of them, many physiological and pathological phenomena, will appear altogether unintelligible.

The sciences more strictly medical, and therefore indispensable, are, general pathology, physiology, and anatomy, particularly the anatomy of the tissues and viscera in their healthy state, which has hitherto been too much neglected, and which has begun to be properly regarded only, since pathology has been more carefully studied. How can any person know a particular tissue to be diseased, if he be ignorant of its characters in its healthy state? How can he distinguish the effects of disease from those changes which occur after death has taken place, if he does not possess correct notions of each, and of the anatomical characters which are peculiar to them? Until anatomy is studied in this way, disputes and controversies will go on, as they hitherto have done, and medicine will make no real progress towards improvement. These remarks apply with at least equal force to pathological anatomy, without a knowledge of which it is quite impossible to give precise and detailed statements of the various alterations of which the tissues and organs are susceptible, or avoid confounding the different structural lesions which occur in them.

These, however, he continues are not the only requisites which an observer should possess. He should be acquainted with materia medica, surgery, "Hygiene," and above all pathology, without which, he can establish no claim to the character he assumes; and still it is by observation only that he can become a pathologist."

We need not inform you, gentlemen, that all the above named qualities which the good medical observer is said to require, are indispensably necessary to the surgeon; but besides possessing all the attainments which a physician's occupations demand, the surgeon must have some important additional acquisitions to fit him for his peculiar pursuits.

In Martinet's remarks, descriptive and surgical anatomy, are not of course peculiarly insisted upon as of great importance to the ordinary medical observer; they are, however, of the utmost moment to the operating surgeon, who, attempting anything without them, might be compared to an ignorant countryman—who, without apprenticeship or previous study, should at once be dubbed engineer, take his place on the railway, and have the lives of a whole train entrusted to him.

Fortunately for our profession, as well as for every other, since the time when Martinet penned his little book, the system of general education has been very much improved, and this begins indirectly to tell on the special education of medical men. In the present state of some of the collateral sciences, which it is incumbent on surgeons to acquire, there begins now to be felt a want of a more extended knowledge of mathematics, which has long been regarded as the best source of severe mental discipline, and is, indeed, the grand

enemy of intellectual feebleness, and credulity: we ought gladly then to hail the day, when with better curricula of medical education this, so called, science of demonstration and truth, will be placed at the head of medical pursuits, as it were watching with a keen glance, the condition and progress of all associated studies; then will conviction in medical science, be measured more regularly, by the value of evidence, men will no longer generalise without particulars,—facts will not, without reason, bend to previously established opinions; never mind whence it came, or who were its authors, when theories in the good sense of the term, will be common, founded on inferences drawn from principles which have been established on independent evidence,—but hypotheses exceedingly scarce.

From such observations, somewhat irregularly brought together, you may form some idea of the general and special attainments which we consider the surgeon to require.

The pleasures of anatomical pursuits have lately been much increased by the application of the microscope, and from a notice we observe in the last number of a valuable periodical, the MEDICAL TIMES, it appears that a course of lectures, by Professor Serres, is about to be published in that Journal, "on the Generation of Organs," which will be likely in its connection with general embryology, to throw a peculiar charm upon the study of the anatomy and physiology of development, and afford a ground-work for more scientific zoological investigations.

Before we conclude, let us return for a moment, to matters more peculiarly connected with operative surgery.

This, it must be borne in mind, is merely the manual or mechanical branch of therapeutics, the other divisions being the dietetic and pharmaceutic, and it is of the utmost importance, that we should remember, that a skill to avoid operations, especially, the more painful and mangling ones, is more valuable to the practitioner and to mankind, than the greatest adroitness in manipulation, or the most brilliant surgical display. Let not the surgical student be over dazzled with the sheen of the catlin, or other polished and glittering weapon; but let him ever bear in mind that one of the best and greatest boasts of modern surgery, is the saving of limbs, which our predecessors were accustomed to lop off, so that in the treatment of some serious forms of disease and accident, the other departments of therapeutics have of late, more especially, declared their power and rights; the number of operations being relatively lessened, and the living monuments of imperfect surgery, coming now less frequently in our way.

Indeed it might be said, that the best surgeon is he who cures the greatest number of diseases, with the smallest number of operations, and certainly there can be no comparison between the triumph of the man who has removed a limb boldly and well, and that of another who might have suggested some mode of treatment, by which the member once doomed to amputation, should be saved, and the patient spared the enormous suffering of the operation, and the appalling mutilation which succeeds, "*Operiren heisst: durch operation heilen*," or operating, is curing by operation, is a remark of Jungken, whose name we had occasion to mention before,—and this would form a fitting motto for every work on operative surgery, tending to keep before us the great and good object of operations, and to prevent our esteeming anything belonging to them which has not lasting utility in view.

We have before remarked on the education and training of the hand, but the most adroit and best educated hand in operative surgery, would be dangerous rather than useful, unless guided by a corresponding head; a thorough knowledge of pathology then, and of all the means which assist diagnosis, let us again repeat are indispensable; the surgeon should act like the Captain of Tasso; "Col senno e con la mano;" and as we have not time to enter upon any discussion respecting the *savoir faire* of the profession, let it be once for all remembered that it is equally his duty to think before he acts, and before he speaks.

Before, gentlemen, I take leave of you, and wish you every success that your labours may merit,—and every good fortune that the favour of heaven may shower on your noble career,—let me strongly recommend to you an untiring industry, methodic study, and an ever zealous love of knowledge, remembering in addition to what we have said, these few words of our famed countryman Bacon. "The pleasure and delight of knowledge, it far surpasseth all other in nature. We see in all other pleasures there is satiety; and after they be used, their verdure departeth, which showeth well that they be but deceits of pleasure, and not pleasures; and that it was the novelty which pleased, not the quality; and therefore we see that voluptuous men turn friars; and ambitious princes turn melancholy. But of knowledge there is no satiety, but satisfaction and appetite are perpetually interchangeable."

COURSE OF LECTURES ON THE THEORY AND PRACTICE OF MEDICINE.

Delivered by C. J. B. WILLIAMS, M.D., F.R.S., Professor of the Practice of Medicine, and of Clinical Medicine, at University College.

(Continued from page 16.)

WE found that in congestion the vessels were *enlarged*, and the motion of the blood *diminished*, so that redness, swelling, pain, and also some degree of heat were present; but in inflammation, the motion of the blood is increased, the sensibility much exalted, the heat considerable, and the secretion increased—the function of secretion is nearly always *impaired* by congestion, so that on the whole we see a great distinction between *inflammation* and congestion. Again, it differs from *determination;* for although in determination the vessels may be enlarged, and the motion increased, and the heat and sensibility exalted, still there is one grand point of difference between it and inflammation, viz., that in the latter there is an alteration in the *products* of the part—it is the tendency to the *exudation of lymph* that especially characterises inflammation. The state of the *vessels* also differs somewhat from that of determination, inasmuch as in inflammation there is *partial obstruction* to the flow of blood, and, as a consequence, partial accumulation giving rise to increased tension and redness. There have been various opinions as to the *causes* of this condition of the vessels. Cullen concluded that the obstruction was owing to spasm of the extreme vessels, and that the "vis medicatrix" struggling against the obstruction, was the cause of the inflammation. But this view is quite out of the question, seeing that there is *no spasm* of the extreme vessels, but rather a *relaxation* or *dilatation*. Hunter knew that the vessels were enlarged, and thought there was something *active* in the process. He called it "active dilatation." Kaltenbruenner had a nearly similar idea, he called it "active or inflammatory erection." Doctors Thomson and Hastings observed, that the immediate effects of the application of an irritant was *contraction* of the vessels with increased motion, which was soon followed by dilatation and diminished motion. These last two observers have rather confounded the effects seen in the *arteries* with those seen in the *capillaries*.

M. Gendrin has shewn that *obstruction* is one of the most important features in inflammation: he also noticed that the *quality* of the blood itself was changed—that the red particles become altered in shape, presenting a ragged appearance at their edges, and that they, as well as the serum containing them, became effused into the surrounding tissues. He states also, that colourless globules were detected in the large vessels, and that if the inflammation was intense, the blood became stagnant, and at length brown, and that some of the red particles became softened, opaque, and, finally, converted into globules of *pus*. Kaltenbruenner says, that if obstruction has not proceeded to stagnation, the motion becomes oscillatory, and that on the subsidence of the inflammation the usual movement of the blood is restored, its former activity being resumed; but if the inflammation continues, and the capillaries remain enlarged, he finds that they present a *tortuous* appearance, and Mr. Kiernan believes that little diverticula of varying shapes are thrown out by the capillary vessels, and that from these diverticula new vessels proceed.

It has been ascertained that the blood flows in greater quantity, and with greater force to and from a part that is inflamed, and that the arteries are enlarged, and pulsate with increased strength. Dr. Alison measured a number of arteries in inflamed limbs, and found that their diameter was decidedly greater than that of the arteries in a corresponding *un*inflamed limb; this proves clearly that the flow *to* the inflamed part was augmented. Again, that there is an increased flow of blood *from* an inflamed part was shewn by Mr. Lawrence. He bled a man who had an inflamed hand from a similar orifice in both arms, and found that from the arm of the inflamed side he obtained nearly three times as much blood as from the uninflamed one (in the same period.)

I have recently found that a stimulus applied to the web of a frog's foot, causes contraction, and diminished motion in the vessels to which the arteries lead, followed speedily by *dilatation* of the vessels, and an *increased* flow through them. If the stimulus applied be too powerful, it causes sudden enlargement of the capillaries and stagnation of their contents—these vessels also became *tortuous*. The arteries do not seem at first to partake of the increased calibre, but, in a few seconds, they enlarge and appear multiplied in number—the blood gushes forcibly along them, and continues pulsating at the opening of the capillaries, which are so much congested as to prevent the passage of the arterial blood through them, and consequently it has to find its way along the *adjoining* vessels, which themselves become enlarged. It is remarkable, that although the force of the circulation goes off through the adjoining vessels, there is still some force applied to the natural channels and communicated backwards from the unadmitting capillaries, which constant effort and repulsion, give rise to the oscillatory movement that I told you Kaltenbruenner has described. The result of this continued attempt at injection is to dilate the capillaries to a greater and greater degree, and if any vessels were previously so small as to escape notice, it is no wonder that they should now become dilated, and be rendered most easily visible. The deductions that we are necessarily led to make from these appearances, are,—1st. That no inflammation can exist without enlargement of the capillaries, and, therefore, that such enlargement, or, in one word, *congestion*, is one of the essential elements of inflammation; and 2dly. That there is no inflammation without enlargement

of the arteries leading to the capillaries of the affected part, or, in one word, without *determination*, which is, therefore, the other element of our subject. Now these two elements combined, viz., congestion and determination, will, if not soon relieved by secretion, flux, or hæmorrhage, inevitably cause *inflammation*.

We may ask, *why* is there a retarded flow of blood under these circumstances? How comes it that the blood should stagnate? I must confess, gentlemen, that this is the *sticking* point, both to the *red* particles, and also to the physiologist and pathologist. Why, again, should the functions of the part be exalted if he circulation is obstructed? Some have imagined that the blood possesses a self-motory power, whereby it may be attracted and revived, and that in the case of *determination*, the vital fluid is determined to go to a particular portion of the system, and thus the particles become aggregated in certain situations.

It is rather a singular explanation, and evinces a very strong determination on the part of its author to get over the difficulty. For my own part, I have never seen any motions in the blood that might not justly be attributed either to the action of the heart, or to certain physical properties. I shall proceed with this subject at our next meeting.

ORFILA'S LECTURES ON ARSENIC.

Containing an Account of the different Operations performed upon the Body of Laffarge.

Collected and Translated by JOHN DAL PIAZ, Pharmacien and Laureate of the School of Paris.

Lecture VII.

Gentlemen,—If you were interested in the question of the purity of reagents, in that of arsenuretted soils, and in the solution of the following problem, *viz.*, How can it be recognized that arsenious acid has been introduced into the digestive canal after death?—you will, I am persuaded, be still more interested in the

Question of Normal Arsenic.—It is two years since Monsieur Couerbe asserted in my laboratory, and in presence of Messrs. Lesueur and Barruel, that normal arsenic existed in human bones: in October, 1839, Monsieur Couerbe again repeated this assertion, though somewhat different. He then said arsenic was developed during the putrefaction of bodies.

The first of these assertions was founded upon the following experiment:—M. Couerbe submitted to the action of Marsh's apparatus, some bi-phosphate of lime, which had been a long time in my laboratory, and carelessly preserved; from this he obtained real arsenical stains. Wishing to verify the results of the experiments made by this gentleman, I made several analyses of bones obtained from the pavilions of the faculty, and from these I obtained arsenic, which was inspected by Messrs. Bussy, Chevalier, and Dumas. I was convinced from this, that normal arsenic existed in human bones, and even announced it as a well-confirmed fact. I had quite given up the idea of pursuing this subject any further, when, in November last, I had to perform a series of experiments before a commission of the Royal Academy of Sciences; amongst them, were those relating to normal arsenic.

My experiments were performed exactly as before; but, to my great astonishment, I was not able to obtain a trace of arsenic, and, after many fruitless attempts, I was obliged to request a delay of eight days; this was immediately granted. During that period I made numerous analyses, but all were attended with negative results; in no instance could I find arsenic in the bones collected for that purpose. In what way was I then to account for the presence of arsenic detected by the first experiments? I was certain all my reagents were of the utmost purity, but I was not convinced of the purity of the bi-phosphate of lime* which had been used by Monsieur Couerbe; finally, I thought the bones I had operated upon at first, might be those of individuals who had been under arsenical treatment, such as is prescribed at the hospital Saint Louis, or again that they might have been the bones of a person who had been fed upon bread, prepared with wheat which had been limed with arsenious acid. I was, indeed, quite astounded, and did not know what to think.

I next procured the bones of a man who had lived and died in the department of La Somme, where the wheat for sowing is always prepared with arsenious acid; but these again yielded no arsenic. Seeing this I was induced to change my opinion upon the subject, and, after numerous other experiments, I sent a memoir to the academy; this has not yet been unsealed.

It results from what I have just stated, that arsenic cannot be detected in bones when these are in a normal state; consequently all objections resting upon arsenic in a normal state, and made in the interest of an accused, are of no value.

Messrs. Flandin and Danger asserted some time after I had made my researches, that arsenic could not be detected in the bones, the viscera or the muscles, however delicate the re-agents might be for detecting this poison. But is it possible, as it is stated in a letter published by Monsieur Couerbe, that this metal is formed during the putrefaction of soft parts of the body? Certainly not! The most delicate investigations have never been able to demonstrate this as true, and I shall content myself by citing an example to prove the contrary of this gentleman's assertion.

The body of a man suspected to have been poisoned by arsenious acid was exhumed by order of the judiciary authorities of Bourbon Vendeé the corpse was in a very advanced stage of putrefaction (it had been ten months under ground) when it was sent to us for examination, and, notwithstanding the most delicate means were resorted to, not a trace of arsenic was discovered. Now if it were true, as Monsieur Couerbe states, that this metal is developed during putrefaction, we ought certainly to have found it in this case.

We shall terminate the medico-legal question of arsenious acid, by endeavouring to refute the last two objections. The first is contained in the following question:—May not the arsenic found in a body have been administered daily for some time as a medicine? Gentlemen, I can affirm, if an individual under arsenical treatment has abstained from the use of this medicine two months, or even six weeks, previous to his death, not the slightest portion of arsenic can be detected in any parts of the viscera; all will have been voided by the urine, the perspiration, and by the stools. But supposing such a case really occurred, then the experimentor could only affirm that arsenic existed in the body, and if the tribunal wished him to declare whether he considered it a case of poisoning or not, he must be assisted by the medical man who attended the deceased during life. Being thus acquainted with the length of illness, the symptoms observed, the lesions found at the *post-mortem* examination, &c., &c., he may then safely draw a rigorous conclusion.

The second objection is one offered by Monsieur Paillet upon the trial of Madame Laffarge; this same objection might certainly again occur.

Monsieur Paillet wished to know whether the arsenic found in Monsieur Laffarge's body, might not have been derived from the minerals daily melted in his furnaces, whether the volatilized arsenic might not have been absorbed by the lungs during respiration: this objection has been much noticed, nevertheless it is of no value, and may be easily refuted.

In the first place, the presence of arsenic could not be detected in the minerals employed at the forges of Glandier; but admit for a moment that arsenic did exist in combination with the minerals, it is certainly impossible the vapours could be inhaled; let us only reflect upon the mode of procedure for extracting the metal. The ore is strongly heated in a large vessel, which is placed upon a high furnace: the vapours produced could not influence Monsieur Laffarge, who was at the base of this furnace, probably at a distance of 100 feet from the exhalations, which certainly would not descend to him, but, on the contrary, would be carried off at a great height in the atmosphere. Even suppose again a small quantity of arsenic had been inhaled in this way, which is an absurd supposition, could the poison have been retained in the body for 55 days, during which time he never went near his furnaces? Most assuredly not. We know it would have been entirely voided by the urine, &c., &c.

I believe I have now stated all that is necessary concerning the medico-legal question of arsenious acid, which we have studied rather minutely, and I hope you have derived some beneficial information from what I have endeavoured to explain. I shall now commence upon the

Symptoms observed upon persons poisoned by arsenious acid.—The first and most ordinary symptoms are, nausea, frequent and abundant vomiting, pain in the epigastrium, and occasional stools, particularly in those cases when vomiting is not very abundant. Gentlemen, I cannot proceed any further without saying I consider a medical man is to be much blamed, if being called to attend upon a patient taken suddenly ill, and labouring under these symptoms, he does not immediately ask himself whether it may not be a case of poisoning, but allows the ejected matter to be thrown away.

Unfortunately it seldom occurs that, if the patient is of a high rank, any one will for one moment suspect him of being poisoned, whilst if such symptoms are observed upon an individual of a humbler class, the medical attendant, and others as well, are even too often disposed to see in these, very rigorous indications of poisoning. But I now continue with the symptoms; cramps and convulsive movements, with fever and intense heat of the skin, soon arrive, and if a large dose of the poison has been administered, the skin may be covered with pustulous eruptions, attended with intense thirst; sometimes the patient becomes cold and insensible, the face becomes blue and much swollen, but the most remarkable symptom is the derangement in the circulation: the heart and pulse beat in the most irregular manner. Sometimes the convulsions cease, and are replaced by syncopes, or a false calm; the body becomes covered with a cold perspiration, the pulse gradually sinks, and finally the patient dies from prostration. Nevertheless, such does not always occur; death often takes place when the patient is a prey to the most violent symptoms, the convulsions may become more and more horrible, in fact he may die in the midst of intense suffering: it has even been observed that the body becomes of a blue colour, as in cases of cholera. This was observed upon Soufflard* who had taken a powerful dose of arsenious acid.

Another symptom to be observed is that of the urinary secretion; the quantity of urine found is not always considerable, generally the patient voids only a small quantity impregnated with the poison. In many cases the urine is red, and tinged with blood, and the secretion is painful; this last symptom was observed upon M. Laffarge. At other times the urine is abundantly secreted, and may be voided without pain. In nearly all cases arsenious acid exists in the urine, particularly when vomiting and purging have not occurred. Another case has been cited, but this very seldom occurs. An individual has been known to have taken arsenious acid at eight or nine o'clock in the morning, and afterwards to have followed his usual occupations until three or four in the afternoon, when he has been suddenly taken ill, and two hours afterwards has died without vomiting anything. Let us now examine the

Pathological changes observed.—Death may ensue from arsenious acid without there being formed in

* This salt is obtained by treating calcined bones, 12 parts, with 9 of concentrated sulphuric acid, and 20 of water. Let these materials be stirred together, and simmered for about six hours; then strain and wash the residue till the water ceases to taste acid. Evaporate the strained liquor, and when reduced to half its bulk, let it cool. A white sediment of sulphate of lime will form, which must be allowed to subside. The clear solution must be afterwards decanted, and then evaporated until it has acquired the consistence of soft honey. It is then taken off the fire, and introduced into wide mouthed stoppered bottles.

* A prisoner who, to avoid the penalty of the law, swallowed a large quantity of arsenious acid during a sitting of the tribunal.

the digestive canal either traces of inflammation, ecchymosis, or eschars, &c. This is not commonly the case; generally pathological changes are very evident, the mucous membrane of the stomach is inflamed as far as the œsophagus, several of the folds of the stomach have a brown appearance, the other parts of the digestive tube being more or less inflamed.

If the poison has been introduced in the state of powder, ecchymosis and even eschars may sometimes be observed. In the stomach of Therese Rigal, for example, there were found about fifty eschars, of the size of a pin's head, although she had vomited continually for nearly five days. In such cases the arsenious acid acts as a caustic.

The heart will generally offer red stains, of the nature of ecchymosis, such as may be observed in the heart of this dog poisoned by arsenious acid. Such are, gentlemen, the questions by the aid of which you may be able, without the least hesitation, to assert as follows:—

In the capacity of a chemist I have extracted the poison I now present to you, and in the capacity of a medical man I have observed the symptoms and pathological lesions which characterize poisoning by arsenious acid. I, therefore, affirm, that such poisoning has been effected. It now remains for us to discuss the best

Mode of treatment to be followed in cases of poisoning by arsenious acid.—The treatment may be divided into two periods; in the first, the poison should be attacked in the stomach by chemical agents, and then evacuated by purging or vomiting. The second period exists when you have not arrived in time to administer the counter-poison, consequently absorption has taken place, and however strenuous your efforts, the patient may die.

In commencing with the first period, we naturally ask ourselves if there really is an antidote for arsenious acid; but before proceeding any further, allow me to explain what may be understood by an antidote?

It is a substance capable of decomposing a poison, or combining with it, at the mean temperature of the stomach, or even at an inferior one, in such a manner as to constitute a new product, which can exercise no deleterious action upon the animal economy. There are two kinds of antidotes; 1st.—those which entirely annihilate the deleterious property of the poison; 2, those which diminish this property in a very sensible manner.

The first are those which, by any operation whatever, will form a new substance. For example, if an individual were to take a certain quantity of chloride of barium, and that sulphate of soda was administered immediately, there would be formed two new compounds—sulphate of Barytes, insoluble, and consequently inert, and chloride of sodium.

The second are those which do not transform the poison into a new product, but combine with it to form a compound possessing much less active properties. For example, an individual has taken corrosive sublimate, and immediately after, albumen is administered; there is then formed a new compound,* having a much less deleterious action upon the economy, nevertheless it is still sufficiently deleterious to cause death in case it should be allowed to remain in the stomach.

These facts being once well established, I again ask if there is an antidote of the first class for arsenious acid?

Unfortunately there is not: the peroxide of iron,* which has been administered sometimes with success, can only be considered as an antidote of the second class.

This peroxide occurs under the 3 following states:

1. The anhydrous peroxide, commonly called colcothar.
2. The dried hydrated peroxide.
3. The hydrated peroxide in magma or jelly.

Of these three the two last are only fit to be used in cases of poisoning by arsenious acid; the dried hydrate should always be administered in preference to that in magma, for it is much more convenient, and can be given in large quantity under a small volume.

It often happens that pharmaciens have no other peroxide of iron than the colcothar, which, in some cases, has been administered to patients. This even occurred during the illness of Monsieur Laffarge, and from that, certain persons were anxious to conclude that the arsenic we obtained was derived from the colcothar. This I will speak of again

The following are the results of numerous experiments:—

Half a grain of arsenious acid was boiled with half an ounce of the hydrated peroxide of iron in magma: in this case the quantity of iron was not sufficient to absorb the whole of the poison. The same weight of the dried hydrated peroxide, mixed with a sufficient quantity of water, was exposed with 12 grs. of arsenious acid, to a temperature corresponding to that of the interior of the stomach, and after a protracted contact of 24 hours, the whole of the poison was absorbed, forming arsenite of iron. If the dried hydrated peroxide of iron acts in such a manner, without doubt its administration will produce good results; it will enable the patient to wait until more efficacious means can be resorted to, as vomiting, &c. If this was not effected, death might still occur, although the action of the poison might be slow; the arsenite of iron thus formed is deleterious; it is attacked by the lactic and chlorhydric acids existing in the stomach, and these, combining with the oxide of iron, liberate the arsenious acid, which is then immediately absorbed. It is for this reason that a much larger quantity of the peroxide than is sufficient to absorb the poison, is recommended; the acids of the stomach, acting in preference upon the non-combined peroxide, do not attack that which is associated with the arsenious acid.

The peroxide thus administered must be evacuated by vomiting, effected by Tartar emetic, or by tickling the throat with a feather: a fresh portion of the peroxide must be again administered, and the evacuation repeated; afterwards operate upon the bowels with castor-oil. Should the patient be under the influence of a strong reaction, copious bleedings must be resorted to. Finally, have recourse to diuretics, by which the poison, if absorbed, may be expelled with the urine; for it has been proved by experience, that, in cases when animals poisoned by arsenious acid have voided a large quantity of urine, they have not died.

Such is, gentlemen, the mode of treatment I advise you to follow. It has been much criticized, the bleeding, in particular, has been much condemned. It has been said that, by bleeding, the life of the patient is unavoidably destroyed. Nevertheless, I can affirm, in nineteen cases out of twenty, when I have bled, the patient has recovered. English medical journals also mention many cases cured by bleeding. But as a substitute for this method, certain persons (amongst whom I may mention Monsieur Jacobini, in Italy, and Monsieur Rogetta, in France,) have tried an Italian mode, founded upon Monsieur Rasori's view of this subject. This gentleman asserts that the symptoms of arsenical intoxication are those of intense asthenia, produced by the action exercised by the poison whilst passing into the circulation, consequently the anti-phlogistic treatment is dangerous; to overcome the symptoms it is necessary to administer broth and brandy.

In the next lecture we shall see if any good can be derived from such a mode of treatment,—for my part, I look upon it as a dream.

* This compound is a combination of albumen, with corrosive sublimate; it is very little soluble in water, but is readily dissolved by an excess of albumen; consequently, the administration of too large a quantity of this substance must be attended with bad effects, in cases of poisoning by corrosive sublimate. This albuminous compound was formerly believed to contain no corrosive sublimate, it was thought that the mercurial salt was reduced by the albumen to the state of calomel; but this opinion is found to be quite erroneous. It is now generally admitted to be a compound of albumen and corrosive sublimate, which, according to Monsiur Lassaigne, is composed of 93.55 parts of albumen, with 6.43 of the mercurial salt.

* This should be prepared in the following manner:—Cause a stream of sulphuretted hydrogen gas to pass for a long time through a filtrated solution of proto-sulphate of iron. This gas will precipitate all the arsenic, lead, magnesia, &c., which might have been associated with the iron salt. Then boil until the solution affords no smell of the sulphuretted gas, and allow it to stand for a day; after which time separate the precipitate by filtration, and evaporate the filtered solution until it has become fit to crystallize; when it must be allowed to stand in a cool place till the crystals are formed.

Collect these, and pour upon them a sufficient quantity of nitric acid to convert all the protoxide into sesqui-oxide. Then, dilute with distilled water, and by adding an excess of aqua ammoniae, a brown gelatinous precipitate will be produced, which, after being washed for a long time with pure distilled water, may then be administered in cases of poisoning by arsenious acid.

It is by exposing this same gelatinous peroxide to a gentle heat, that I obtain the dried hydrated peroxide, which I recommend in preference to the gelatinous, on account of its being more convenient to administer in large quantities.—*From Orfila's Lecture on Iron and its Compounds.*

IRISH INTRAMURAL INTERMENTS.

To the Editor of the 'Medical Times.'

Dr. Sir,—I was highly gratified to perceive that your efforts for the extinction of "intramural interments" have been productive of so unexpected a result as the preparation of Mr. Mackinnon's Bill, yet it surprised me to perceive that by its clauses the operations appear to be confined to England. In this I may be wrong, and if so, you will excuse me for intruding upon you. There is no part of the world in which burial grounds are more neglected than in Ireland, and few places where the effects of such neglect have produced more ill consequences to human health and comfort than in its towns through which (speaking generally of the country) burial grounds are thickly distributed. It would, therefore, be a monstrous error in the application of this measure, if its benefits were not conferred upon Ireland—to which particular I beg the liberty of calling your attention. In clause 6, "the parochial committees of health" are composed of *clergymen and churchwardens only*, which I presume is a positive defect, inasmuch as there should be or ought to be, upon a committee, in whose hands so important a trust is reposed, some individuals whose education embraced the operations of physical nature upon the human constitution, and medical men are generally best informed upon these subjects—the addition, therefore, of a few medical men to these parochial committees of health, would be, in my opinion, an improvement.

On the interment of "eminent men" in "Westminster Abbey, or St. Paul's Cathedral," a few words may not be out of place.

Under any circumstance the burial of mankind under the roof where living creatures so frequently assemble in numbers, is an evil, and ought to be abolished even in the case of "eminent men." A great national building should exist in these countries for the deposit of their illustrious dead, and for the erection of proper monuments to their memories, which should be under the controul of Government only. Westminster Abbey is not the place for such deposits; besides monuments have been refused a place in that celebrated edifice. The late Dr. Ireland, for instance, refused to allow a monument to be erected to one of the greatest poets, next to Milton, which Britain ever had, viz., Lord Byron. To prevent such capricious exercise of power in individuals, and to separate the dead from the resort of assemblies of the living, I think the nation should erect an appropriate receptacle for such mementos, and for the remains of men whose lives have been sufficiently distinguished in its history. There is a man now living, whose name it does not become me to mention, whose glory requires no earthly monument to perpetuate, and whose remains when his country shall be deprived of his services, ought to be *the first* to render memorable such a memento of human greatness, and where succeeding warriors would desire a resting place. Hoping you will excuse this intrusion,—I remain, dear Sir, truly yours,

W. R. Gore.

Cecil Street, Limerick,
Sept. 26th, 1842.

TO CORRESPONDENTS.

Vol VII.—*It is our intention to complete, in the present Volume, the course of twenty-four lectures by Professor Owen, on the Comparative Anatomy and Physiology of the Nervous System—the course by Professor Serres (consisting of about* 10 *lectures) on Organogeny—the course by Orfila, on Arsenic (the last lecture, but one, of which, we give this week)—with the course by Mr. Nottingham, on Operative Surgery. The lectures by Dr. C. J. B. Williams, and Doctor Scoffern, will probably extend to the next volume.*

Mr. Atkinson.—*The note, with the intimation referred to, was received, but the latter was forgotten when the paper came under consideration subsequently. The portion omitted, was omitted on the ground that the best answer to objections are facts strongly evidenced. People do not so much ask, are such things possible? but, do they exist? The last demonstrated—logic tells us the first cannot be disputed.*

Nulli Secundus.—*We believe, but are not certain, that Mr. Dermott, the lecturer, was the editor and principal proprietor of the* Medical Record. *It extended to four or five numbers. Our price and circulation must make all such speculations losses.*

Beta.—*We have heard, from other quarters, of Mr. Jackson's frenzy. Our review of his work was of course just, but marked by much kindness for his inexperience and zeal; and, if in full possession of his mind, he would have felt himself under a serious obligation to us. The young man has evidently just enough of talent to make him conceited, and just enough of active folly to make him an object of anxiety to his friends.*

A Student.—*We know of no* cheaper *mode of passing the first winter session than by confining the entries to hospital practice (3 years), say* £26 10s.—*Anatomy and* Demonstrations, *for the season,* £5 5s.; *Chemistry,* £4 4s., *and* Materia Medica. *These are all the courses* absolutely necessary *for the first session. Of course, without great* reason, *the pupil will not confine himself to these entries. The hospital practice should be entered to immediately.*

A. T. H. T.—*We denied once before that Dr. Weatherhead had anything to do with the editorship of the* Medical Times. *In consequence of a rumour to the contrary, we once more feel it necessary to asseverate our denial.*

Mr. R. Mason.—*This gentleman furnishes us with what he calls an* important discovery. *He considers the first cause of disease to be ignorance of the art of breathing. We have some recollection of an Irishman, who, extending the principle, more wittily explained by it the phenomena of* death. *The second cause is, ignorance of the uses of saliva! The third, of sleep. Mouth-breathing people are lean, sickly, &c.; nostril-breathers, healthy, &c. The rationale is the increased moisture produced by the latter mode, and which offers the* satisfactory *explanation of these* established *facts.* "Sleep," *adds our author,* "is produced by keeping the mouth open, consequently prevented by keeping the mouth closed, the saliva-passages, by the first process, being kept dry." *Here is* "*Sleep at Will*" *produced by a very simple process. We are promised further details, but must decline them, on the plea that those already given are likely to completely appease our readers' curiosity.*

Mr. B.—Morus—Mr. H. C.—Academicus—Carus Redivivus, — Investigator — Anti-Humbug, — Petrus—A Quack Doctor—An Owner of a Burial Ground—A. B. C.—A King's College Student—Anti-Toddite,—*declined for want of space.*

Will Scrutator *scrutinize his own conscience before asking us to publish such details—and so unsupported—against an unassuming, and, we believe, extremely well-meaning medical practitioner.*

Sigma *sends us an authorized account of the offer made to him (an extremely experienced and well educated apothecary, with the best recommendations) by a gentleman proposing to have his services as an assistant.* "After walking four miles," *he says,* "and waiting forty minutes, I had some converse with a party calling himself a gentleman, who lives not more than 100 miles from Finsbury, and has a branch establishment (a shop) not 50 from Bethnal-Green Road—and was astonished at the liberality of his offer for such very trivial services as were required—the duties being merely 'superintending' and 'pushing' the 'retail business,' from 7 morning till 11 night—dispensing the medicines—attending counter practice, casualties, and midwifery for a public institution—besides furnishing the house, PAYING THE TAXES, and feeding and clothing myself,—for FIFTY POUNDS A-YEAR!!! *The poor assistant is a married man too. Alas! for our respectable profession!*

O.—*We hope yet to give the conclusion of the paper referred to. The delay originates in a breach of engagement, over which we could exercise no useful control.*

H. B. W. *sends us a strongly-written protest against the delay in the publication of* "*Turner's Chemistry*" *and* "*Copland's Dictionary.*" *He is particularly anxious to know whether the fault lie with the authors or publishers, and, in either case, to have it remedied. Part 5, No. 4, of Turner's work, was promised, he says, for Autumn,* 1841, *and is not yet published, commencing the Winter,* 1842!

Dr. Scoffern's Lecture, *our* Weekly Periscope, *and our* Extracts from the German and French Journals, *are unavoidably postponed till next week.*

Other correspondents will be answered next week.

ERRATA.

In consequence of the haste with which our first impression was sent to press last week, several typographical errors were left uncorrected. The page of "Medical Mems," binding in between pages 6 and 7, should have been numbered 7 and 8, instead of 6 and 7. The other errors are so obvious, that they may be safely left to the correction of the reader.

THE MEDICAL TIMES.

SATURDAY, OCTOBER 8, 1842.

Quem vero arripuit, tenet, occiditque legendo
Non missura cutem nisi plena cruoris hirudo.

* * * * *

Qui studet optatam cursu contingere metam
Multa tulit, fecitque puer; sudavit et alsit;
Abstinuit venere et vino.

THERE are three aspects in which the present session invites attention; the lecturers—the pupils—the corporations. A word or two on each.

Having very recently discharged our bile on the mode of election and general character of the attainments of our lecturers, we may just now leave them out of sight, to say something on a subject of, perhaps, more immediate importance—the *lecturers' duties.* And what are they? In many—alas! too many instances,—the ready answer for the FIRST, is to RESIGN. Numbers of them stand in the places of better men, capable of teaching higher truths,—and to the extent of their unasked, unrequired, but not unobtrusive inferiority, are they accessaries to the virtual extermination of truths—and guilty agents in the manufacture of mischiefs,—in one word they are negative, but real calamities, to their pupils and society. But it would be useless to ask from those we deal with, so stupendous an exercise of conscientiousness, requiring in its agency so impossibly large an absence of vanity and self-love. We must content ourselves with appealing to them, that if they will not give way to higher mental powers—they will at least make the best use of their own. Their pupils have a virtual title to a certain stipulated portion of their time—their knowledge,—and their active industry and labour,—a title, whicl can only be impugned or disregarded witl a proportionate want of fairness, good faith, honour, and common honesty. Ir science, as in everything else brought tc market—there is a certain amount, and a certain quality, which is the purchaser's fair money's worth; and whatever is giver less, or worse than what is thus reciprocally bargained for—is so much swindled. There is this additional circumstance, however, in *medical* science—that health and life, and of immortal beings too,—hang on every step of the descending path of diminution or deterioration! We say then lecturers do your duty. Give to you lectures the importance which, under all circumstances (for evil, if not for good), mus attach to them. Give time to their carefu preparation. Adapt them to your audience in composition and delivery. Be punctua yourselves, and insist on regularity from your pupils, and let the last week of you courses shew as much attention to you duties as the first. To the *gentleman, th man of honour*, the last of these hints i useless; for his sense of personal dignity will preclude his presentation of himsel before his class, as an inconstant, or shuf fling, or mercenary character, as one mor or less attentive, as he is further o nearer removed from the period of pecu niary remuneration. If we would lenc force to our recommendations we would beg lecturers to remember that no where thar in medical teaching is honesty a wise policy. A session's well discharged duty tells on his own knowledge and skill—tell on his future year's classes—tells on hi standing with his profession—his practic among the public—his name—reputation —fame—*everything!*

But if neither personal interest—no high and seriously responsible duties have power over the lecturer—if he be deaf t them, charm they never so wisely, the students will do but ill, who passively submit to the wrong. There need be nc insubordination, though that would be a less evil than the *injustice* we are contem plating; the students have only peacefully to unite together, respectfully, but manfully to remind the lecturer by protest or rounc robin of his neglect of duty; if that fail, tc send their signed statement to us for publi cation, and if the evil survive that step, tc form themselves into a committee or asso ciation to try the matter publicly, by legally SUING THE DELINQUENT FOR BREAC OF CONTRACT. This is a new—and pro bably startling recommendation—but it i justified by the glaring instances of negli gences to which students are too frequently subjected; and by a consideration on the evil consequences, which must inevitably arise out of them. An action at law, i tried in many cases which we have hearc of, would be certain of success: and woulc do a world of good.

Taking a hearty interest in the fortune of our younger friends, the students, we wish our space, or a reasonable allowance of patience, could justify our placing before

these gentlemen, one half of the reasons which recommend steadiness, hard study, and perfect regularity to their warmest acceptance. We have watched annual wave after annual wave of students appear and disappear, and if one truth has been more prominent than another among our observations, it is that the student who will not work, *and work regularly and hard*, is in the position of one who has deliberately chosen to be for the rest of his life a knave or scamp. The raised qualifications at the Hall and College, whatever other qualities they may have, have certainly this,—that there is now no *safe* half-attention to duties,—they allow of no very continuous idleness—and we would suggest that gentlemen who are entering to this or that school, ought, *in mere policy*, at once to make their election between a career of entire dissipated scampishness—and entire healthy, steady application to their professional education. It would spare us much hypocrisy of study and save a wonderful deal of time. For ourselves, we have little more hope for the medical student, occasionally about town, drinking, smoking, billiard playing, and *flashily* dressed, than for the absolutely doomed rake. The same well known —well trodden path is before both, marked by some or all the common adjuncts: an irreparably ruined constitution—pecuniary embarrassments—rejection at the Hall and College—an empirical and impoverished practice—an alienated or impoverished family—enlistment in the army—life of degradation and misery,—*violent death!* One important step—the best guarantee of continuous steadiness,—is the student's comfortable inclusion in the domestic circle of some respectable family. A lone chamber after a day's hard study, gives the tavern and the singing-room an attraction, difficult to resist, save by minds of more than ordinary firmness, and enriched with more than usual internal resources. Whenever, therefore, this great moral and mental advantage can be secured by the student—our earnest advice to him is to clutch it. He will not, of course, in making this selection, overlook a due proximity to the hospital he attends. There can be no objection to moderate ambulatory exercise (which, indeed, the student will find essential to profitable study), but the distance should never make the walk an inconvenience. The numerous lectures demanded by the Hall, backed by the increasing requisitions of the College, leave little time to be spent on the *trottoir*. We conclude our hints to the students, with a warning which should be the motto of their note book,—the ornament of their room,—and as inseparable a companion, as the Phylactery was of the Pharisee. EVERY MOMENT MISPENT—IS ONE CHANCE MORE FOR ILL FORTUNE—*an ill fortune that embraces the future fate of both practitioner and patients.*

This session presents us with two features of striking importance, the diminution of metropolitan—the increase of provincial schools. The Hunterian school—the Sydenham school—the Webb-street or Grainger school,—have each ceased to be; and the larger hospital schools have felt so much fear for their vitality, that they have taken this year extra pains to dazzle the judgment—and secure the support of pupils. Where will all this end, and what will be its effect on the London corporations? One thing is certain; that we may prepare for a brisk competition among the London schools—which will bring about a lower scale of prices, and a better system of medical appointments. The two great evils of medical education will thus have worked their own cure.

We have been asked the probable effect which the requisition of an additional year of study, will have on the fortunes of the College of Surgeons? Very trifling. The facilities offered by the provincial schools, will keep up, if not augment, the class of students; and an education at a distance from the College, will not tend to lessen the estimation of its diplomas. On the principle of "omne ignotum pro magnifico" distance will be apt to give an enchantment to the College, which those living near to it, as ourselves, would in vain endeavour to discern—or appreciate. Individually, however, many of the members of the Council are suffering this session from an unusual diminution of entry fees; and, the only consolation we can extend to them is, the expression of a hope, that their punishment may not extend to more than its present amount,—about the tenth part of their deserts. If, while they had the power, they had adopted a better system of government, London would be shewing a better list of schools,—and a larger class of students.

RECOLLECTIONS OF LIVING MEDICAL MEN.

ANTHONY WHITE, DR. BRIGHT, DR. HAMILTON ROE.

A VOYAGE up the Rhine prevented Probe completing his sketch of the medical officers of the Westminster Hospital as soon as intended. They sadly complain of the torturing state of suspended animation in which they have been kept.

By a remarkable coincidence we find we finished our last sketch with a President of the College; we have now the pleasure of commencing with another. ANTHONY WHITE is quite a different man from George James Guthrie, whom he succeeds. He is, in every respect, a perfect Antithesis. He is about 55 years of age—a stout, comfortable, farmer-like looking personage, of ordinary height, and of ordinary mien; a good-natured face, with rather a pre-possessing, intellectual forehead, upon which the perceptive and reflective organs are well marked. Tony Lumbkin, as some of his friends call him, from his careless, and indifferent manner and attire, is generally considered a good practical surgeon, and has been a good operator.

In his public functions, lazy and indolent, as the Fat Boy in Pickwick, his visits to the hospital are few and far between. When, however, by an unusual and desperate effort, he opens his mouth, his clinique or oral instruction is invaluable. "He drops molten gold—he shoots pearls;" but such an occurrence is an era in the reminiscences of the pupils. He has taken a degree in Cambridge, and has an extensive and aristocratic practice in the West-end, and in the neighbourhood of Parliament Street, where he lives, without even writing, advertising, or puffing for it.

In the time of Quen Anne, there was a class of Politicians, called 'Whimsicals,' who were never in one mood of mind long. In the medical profession there is a similar class now, with this difference—that the latter change and shift their opinions as their interest suggests:—the worthy Tony has been every thing by turns, and nothing *long*. His views were wisely influenced by the prospects that lay before him. When distant from the eminence which he now occupies, they were marvellously comprehensive *indeed;* but as he neared the object of his idolatry, they became very narrow and circumscribed; every step he took towards the road of his greatness, was a confirmation of the correctness of his opinions. "Some achieve greatness; others, have greatness thrust upon them." Not that his passiveness—his good-natured easiness of disposition —his oriental homage to the powers that be, did not deserve some token of regard—some reward. His readiness to oblige his friends—his holy zeal to do battle for the cause of his company—insured his elevation in the rotation of collegiate honors. Some might suppose, that the absence of any literary or scientific labours, or of any intellectual evidence of high and commanding talent, on the part of the candidate, might prove an obstacle to his ambitious aspirations. In this seat of congenial dulness, "a fellow-feeling makes us wondrous kind." A negative merit—a recommendation in their eyes —guaranteed the votes of the majority of the Council. In vain you search the records of the College—the Annals or Archives or medicine—for the name of White. No brochure—no article,—no essay,—no octavo or duodecimo, —exists to enlighten us or posterity upon the views which he entertained, and for which, his admiring and disinterested colleagues placed him in the post of honour and emolument. Hitherto, his talents have been latent. Let us hope that the genius which, has so long slumbered will be evolved, and that seizing the scalpel and tucking up his purple robes, he will engrave his name upon the columns of Fame.

It has been told of a certain cunning Pontiff, that he affected severe bodily indisposition to induce his brother cardinals to elevate him to the chair of St Peter, and that *when elected* he threw off his debility and made them feel the vigour and energy of his rule. May we hope that Anthony, like his illustrious namesake, hath veiled his secret thoughts, and played only a secondary part, making it appear "that he had neither art, nor words, nor worth, action, nor utterance, nor the power of speech to stir men's blood," and, that having gained his object from the impression that his talents could not prove formidable to his friends, he may prove to his mistaken colleagues that he is made of sterner stuff, and wisely presaging the inevitable fate that awaits his obstinate and stupid comperes attempt to effect, and nobly dare to do that, which men of greater reputation, shrink from essaying; and which would tend to unite and satisfy and regenerate the profession, and place him for years at the head and front of all its honours? He finds division, envy, jealousy, and imbecility reigning in the camp, treachery ready to undermine its councils, and expediency, whispering concession of such a paltry nature, that it is only to be proposed, then to be spurned. He sees the council like a crazed ship's crew quarrelling in a storm, while their enemies are within gun-shot. Even this figure affords only a faint idea of the fatal

infatuation of the indecision that exists in the Cabinet of the Monopolists.

Under such circumstances, he must be well aware, that a pertinacious refusal to recognise the right of the great body of surgeons to the principle of self-government, cannot be long withheld, and that it would be prudent to earn their good-willby liberal measures. As President, he can throw some weight into the scale, and, as a matter of course, will be consulted in the contemplated changes We trust he will exert it in the right *cause*. They say he is a good scholar, and well versed in the literature of the ancients. In private life he is all benevolence and gentleness. His time has been all zephyrs and sunshine; and the truth of the moralist's observation is realised in him—

Semita certe,
Tranquilla per virtutem patet unica vitæ.

Prosperity, if it be a test of talent, as many deny, has attended on his exertions. Among his other qualities, strict attention to his own interests is conspicuous. If we were to judge by this, we would hold him to be, provided he could rouse from the stupor of his nature, an able politician.

He has hitherto played a very subordinate part in the politics of the College.

Aston Key has truly observed, that the member can hardly be said to have any connection with the College. It is no alma mater to him. He may long for its honours, but they are beyond his reach. He feels that no industry—no exertion of talent, can place them within his reach. Professor Kidd, that noble-minded, and spirited reformer, has urged similar arguments. And lately a very eloquent writer, and original thinker, Mr. Edwards, has remarked that the council in their diploma certify that the members have received a sound, moral, and professional education; yet they deny the judgment or right to elect those who are to govern them. Anthony White, if he be an honest man, must exert himself to do away with this iniquitous state of things. We trust we shall not have to say of him, "Honores mutant mores."

Dr. Bright, the senior physician, the pupils say, and we agree with them, "is a very nice old fellow;" of quiet, retiring, gentlemanly manners. He has an unconquerable dislike of being followed round the wards by the pupils. They are thus deprived of that instruction to which they are entitled, and for which they have paid. He is a man of great reading, and his mind is deeply imbued with the ennobling spirit of the delightful literature of Greece and Rome.

He never lectures or communicates oral information. He has never appeared in print. The results of his extensive experience are lost to the world. He is totally unsuited to public duties. A rich field of observation is allowed to fallow*. It is another instance of the mismanagement of this institution. He has an independent fortune, and resides in Manchester Square. He is generally esteemed by all who have the pleasure of his acquaintance.

Dr. Hamilton Roe, so called, to distinguish him from the many Roes and Does that abound in this overgrown metropolis, is the second physician. If we had lived in Pagan times, we would have earnestly invoked the aid of the Pierian maids before we would have dared to attempt to delineate this mystical compound of physic and divinity.

He unites in his own person the functions of priest and physician as of old. The Egyptian priests practised medicine, and revealed the results of their experience to each other in hieroglyphics. Dr. Roe practises medicine, and preaches in the unknown tongues. It is an union, which some assert, is incompatible; Dr. Roe makes it answer very well. Le Clere discussed the question, whether medicine came immediately from God? Dr. Roe contends in the affirmative, and that he dispenses it. Such an exalted opinion of his ability, have his votaries, that they think "truths divine come mended from his tongue,"

That his knowledge doth attain,
To something like prophetic strain.

He is about 42 years of age. And of a middle height; with an expressive good-natured, and thoroughly Milesian face. He was born in the county of Wexford, and is "a good man of Ross." Mrs. Hall, in her tour describes them as a race of people, as shrewd, intelligent, good-tempered, and hospitable as are to be found in the whole island; qualities, which we believe, the Doctor does not belie.

His medical brethren charge him with not being quite professionally orthodox, that he is liable to appropriate to himself the results of the investigations of others, (some of which, have been the subject of warm reclamations) and, that he avails himself of the religious infirmities of his fellow-creatures, especially, of the softer sex; and that they have been made auxiliary to his success in his profession.

We believe him to act from conviction in this respect, to a certain extent. The organ of veneration towers over all the others. We ascribe his fanaticism to it. Before even Irving began his insane bellowings, the Doctor was being employed in laying down the trams of a line or railroad that was to carry only first class passengers to heaven at a great pace, by the most direct road; and in the shortest possible time. The Doctor was sole-director. But as there was more extravagance and novelty in Irving's hallucinations, the railroad was abandoned. One of the doctrines was, that fortune and rank were especial marks of Providential regard on earth, and was a passport to favour in the next. It was a new system of evangelical selecticism. The Doctor, now that his great master is no more, holds forth to enraptured Countesses and Dowager Duchesses, who flock like geese to hear the male sybil cackle. These rhapsodical communions are well attended. He first relieves himself with certain inarticulate sounds awfully guttural; a species of unintelligent ventriloquism—then violent convulsive action, flesh, as it were, wrestling with the spirit—then inexpressible rumblings are heard—the silence of the grave reigns—the spirit is speaking. Then the prophet, the plenipotentiary, the interpreter, expounds the will, and explains the meaning of the sounds which appeared so unintelligible. It is here the Doctor shines. He seems touched with Ithuriel's spear; he is warmed with celestial fire. The metamorphosis is so extraordinary, that his intimate friends can hardly recognise him. His action animated, the eye meteoric and instinct with life, kindles, dilates, illuminates his gestures, and spurning the elegant and dignified gracefulness of the stage or rostrum, like the inspired priestess of antiquity on her tripod, he rushes into intense earnestness, carried away, with the whirlwind of his own eloquence. His words rush forth in a tornado; his frame shakes with convulsions; he is terribly in earnest; he is battling inwardly with the Prince of Darkness, and Nature is almost exhausted with the struggle. Anon he lessens in vehemence his fiery energy slackens—his strong devotion involved in pleasing phraseology thrills through the ladies. They are touched with his eloquent electricity. It is contagious animal magnetism. He holds their souls suspended in the blood emotions of a varied character,—enraptures these dear devout susceptible tendrils of humanity and their sympathies, like conducting rods, carry off the excess of his inspiration, and relieve much the excited prophet.

Probe.

* Rather to lie waste, every days neglect being another stage of loss and deterioration.—Ed.

CURABILITY OF CONSUMPTION.

(To the Editor of the 'Medical Times.')

Continuing my practical cases, permit me to mention that in January 1837, Mr. Swain, between 50 and 60 years of age, a confidential clerk in the employment of Messrs. Betts & Co., was seized with influenza. Dr. Ramadge was called in to see him about six months afterwards, when his lungs had been pronounced tuberculated by Dr. T. Davies, who had formerly been his apothecary in Whitechapel, and now regarded his case as hopeless. The only recommendation given by the latter gentleman was to leave town, which Dr, Ramadge disapproved of, as his legs were dropsical, his breathing extremely difficult; there were violent fits of coughing, in which large quantities of purulent matter mixed with blood were brought up. A simple change of air could not remove such a formidable train of symptoms. Without entering into details, it is only necessary to say, that the treatment was conducted on the principle of establishing a wholesome relation between inspiration and expiration, and of meeting constitutional symptoms by appropriate medicines. In about three months he recovered, and resumed the duties of his situation, after an absence of nearly a year.

Mr. A— Deputy-alderman of one of the wards of Cripplegate, consulted in 1834 Dr. Davies for consumption, who advised him to go abroad at the same time intimating to Mr. Stone, the general practitioner in attendance, that he would never recover. He wintered in Nice, and returned home early in the ensuing summer. From inquiries by Dr. Ramadge into the case and its past history, it was discovered that he had gone away with catarrh and a cavity, and returned with the latter only, losing thereby his best protection. He was at this time perspiring at night, and expectorating sanguineous purulent matter. The treatment adopted involved the use of the mechanical process: his chest expanded, the cavity healed up, and all the symptoms disappeared gradually. Two years afterwards, he declared to Dr. Ramadge who was called in for an attack of influenza, that he had never enjoyed better general health, and that all traces of his old disease had vanished.

A child named Ann Cooper, about six years old, residing near Bartholomew's Hospital, daughter of the sextoness of St. John's Church Clerkenwell, was in 1827, brought to Dr. Ramadge under empyema, which had made for itself an opening about two inches below the left nipple and discharged freely for several months, till she had lost at least two or three times her own weight. A cavity had been previously ascertained to exist in the summit of the left lung. Dr. Davies, on being asked his opinion, held out no hopes but merely laid claim to the credit of having seen many such cases, though they are of very rare occurrence. This child was frequently shewn by Dr. Ramadge to his pupils of whom I was one, being considered interesting from its infrequency. She remained in stationary ill-health for many months till at length she was seized with measles, which our preceptor regarded as a favourable occurrence, as it would exert a beneficial influence on her old complaint. The result was that the catarrh which accompanies measles expanded the lungs; the chest, which before hardly measured twenty inches in circumfer-

ce, in two months increased more than three
ches, and the discharge ceased. I have
ely heard that she is still alive and quite
ll. In his lectures at the London Hospital,
. Davies was accustomed to say that he never
ew but two instances of recovery from con-
nption, though some of his pupils men-
ned that they had known cases abandoned
him do remarkably well; and numerous
tances such as those given above, were to
found in the single locality selected.
My object in giving these cases with the
narks attached, is not to present the names
individuals, or their practice, under invi-
us contrast, but to prove what really can
accomplished by the conjoint powers of na-
re and art.

PHILANTHROPOS.

STUDENTS' COLUMNS.

addition to the regulations of the various exa-
ining bodies given late week, we present, at the
quest of a correspondent, the following:—(The
y regulations may be seen in No. 152, Vol. 6.)

REGULATIONS OF THE
ROYAL COLLEGE OF PHYSICIANS OF LONDON.

Every candidate for a diploma in medicine,
on presenting himself for examination, shall
oduce satisfactory evidence—

1. Of unimpeached moral character;
2. Of having completed the twenty-sixth year of his age; and
3. Of having devoted himself for five years, at least, to the study of medicine.

The course of study thus ordered by the College,
mprises,—Anatomy and physiology, the theory
d practice of physic, forensic medicine, che-
stry, materia medica and botany, and the prin-
ples of midwifery and surgery.

With regard to practical medicine, the College
nsiders it essential that each candidate shall
ve diligently attended, for three entire years,
e physicians' practice of some general hospital
Great Britain or Ireland, containing at least
e hundred beds, and having a regular establish-
ent of physicians as well as surgeons.

Candidates who have been educated abroad will
required to show that, in addition to the full
urse of study already specified, they have dili-
ntly attended the physicians' practice in some
neral hospital in this country for at least twelve
onths.

Candidates who have already been engaged in
actice, and have attained the age of forty years,
t have not passed through the complete course
study above described, may be admitted to exa-
nation upon presenting to the censor's board
ch testimonials of character, general and profes-
onal, as shall be satisfactory to the College.

The first examination is in anatomy and physi-
ogy, and is understood to comprise a knowledge
such propositions in any of the physical sciences
have reference to the structure and functions
the human body.

The second examination includes all that relates
the causes and symptoms of diseases, and what-
er portions of the collateral sciences may appear
belong to these subjects.

The third examination relates to the treatment
diseases, including a scientific knowledge of all
e means used for that purpose.

The three examinations are held at separate
eetings of the censor's board. The *viva voce* part
each is carried on in Latin, except when the
ard deems it expedient to put questions in Eng-
h, and permits answers to be returned in the
me language.

The College is desirous that all those who re-
ive its diploma should have had such a previous
ucation as would imply a competent knowledge
Greek, but it does not consider this indispensa-
e, if the other qualifications of the candidate
ove satisfactory; it cannot, however, on any
count, dispense with a familiar knowledge of the
tin language, as constituting an essential part of
iberal education; at the commencement, there-
fore, of each oral examination, the candidate is
called on to translate *viva voce* into Latin a passage
from Hippocrates, Galen, or Aretæus; or, if he
declines this, he is, at any rate, expected to con-
strue into English a portion of the works of
Celsus, or Sydenham, or some other Latin medical
author.

In connection with the oral examinations, the
candidate is required, on three separate days, to
give written answers in English to questions on
the different subjects enumerated above, and to
translate in writing passages from Greek or Latin
books relating to medicine.

Those who are approved at all these examina-
tions will receive the following diploma, under the
common seal of the College:—

Sciant omnes, Nos, A. B. Præsidentem Collegii
Medicorum Londinensis, unà cum consensu So-
ciorum ejusdem, auctoritate nobis a Domino Rege
et Parliamento commissâ, examinasse et appro-
bâsse ornatissimum virum, T. S. et ei concessisse
liberam facultatem et licentiam tam docendi quam
exercendi scientiam et artem medicam, eidemque
summis honoribus et titulis et privilegiis, quæcun-
que hic vel alibi Medicis concedi solent, intra
auctoritatis nostræ limites frui dedisse. In cujus
rei fidem et testimonium, adjectis Censorum et
Registrarii chirographis, sigilum nostrum commune
præsentibus apponi fecimus, datis ex ædibus Col-
legii die mensis anno
Domini millesimo octingentesimo.

(Signed)

STATUTES OF THE UNIVERSITY OF EDINBURGH RELATIVE TO THE DEGREE OF M. D.

Sect. I. No one shall be admitted to the exa-
minations for the degree of doctor of medicine who
has not been engaged in medical study for four
years, during at least six months of each, either in
the University of Edinburgh, or in some other
university where the degree of M. D. is given;
unless, in addition to three anni medici in an uni-
versity, he has attended, during at least six winter
months, the medical or surgical practice of a
general hospital, which accommodates at least
eighty patients, and during the same period a
course of practical anatomy: in which case three
years of university study shall be admitted.

Sect. II. No one shall be admitted to the exa-
minations for the degree of doctor who has not
given sufficient evidence,—

1. That he has studied, once at least, each of the following departments of medical science, under professors of medicine in this or in some other university, as already defined, viz.:—anatomy, chemistry, materia medica and pharmacy, institutes of medicine, practice of medicine, surgery, midwifery and the diseases peculiar to women and children, general pathology, practical anatomy (unless it has been attended in the year of extra academical study allowed by Sect. I,)—during courses of six months; clinical medicine, that is, the treatment of patients in a public hospital under a professor of medicine, by whom lectures on the cases are given—during courses of six months, or two courses of three months; clinical surgery, medical jurisprudence, botany, natural history, including zoology—during courses of at least three months.
2. That in each year of his academical studies in medicine, he has attended at least two of the six months' courses of lectures above specified, or one of these and two of the three months' courses.
3. That, besides the course of clinical medicine already prescribed, he has attended, for at least six months of another year, the medical or surgical practice of a general hospital, either at Edinburgh or elsewhere, which accommodates not fewer than eighty patients.
4. That he has attended, for at least six month, by apprenticeship or otherwise, the art of compounding and dispensing drugs at the laboratory of an hospital, dispensary, member of a surgical college or faculty, licentiate of the London or Dublin Society of Apothecaries, or a professional chemist or druggist.
5. That he has attended, for at least six months, by apprenticeship or otherwise, the out-practice of an hospital, or the practice of a dispensary, or that of a physician, surgeon, or member of the London or Dublin Society of Apothecaries.

Sect. III. No one shall obtain the degree of
doctor who has not studied, in the manner already
prescribed, for at least one year previous to his
graduation, in the University of Edinburgh.

Sect. IV. Every candidate for the degree in
medicine, must deliver before the 24th of March,
of the year in which he proposes to graduate, to
the dean of the faculty of medicine,—

1. A declaration, in his own handwriting, that he is twenty-one years of age, or will be so before the day of graduation: and that he will not be then under articles of apprenticeship to any surgeon or other master.
2. A statement of his studies, as well in literature and philosophy as in medicine, accompanied with proper certificates.
3. A medical dissertation composed by himself, in Latin or English; to be perused by a professor, and subject to his approval.

Sect. V. Before a candidate be examined in
medicine, the medical faculty shall ascertain, by
examination, that he possesses a competent know-
ledge of the Latin language.

Sect. VI. If the faculty be satisfied on the
point, they shall proceed to examine him, either
viva voce, or in writing; first, on anatomy, che-
mistry, botany, institutes of medicine, and natural
history bearing chiefly on zoology; and, secondly,
on materia medica, pathology, practice of medi-
cine, surgery, midwifery, and medical jurisprudence.

Sect. VII. Students who profess themselves
ready to submit to an examination on the first
division on these subjects, at the end of the third
year of their studies, shall be admitted to it at
that time.

Sect. VIII. If any one, at these private exa-
minations, be found unqualified for the degree, he
must study for another year two of the subjects
prescribed in Section II., under professors of medi-
cine, in this or in some other university, as above
defined, before he can be admitted to another
examination.

Sect. IX. Should he be approved of, he will be
allowed, but not required, to print his thesis; and
if printed, forty copies of it must be delivered
before the 25th day of July to the dean of the
medical faculty.

Sect. X. If the candidate have satisfied the
medical faculty, the dean shall lay the proceed-
ings before the Senatus Academicus, by whose
authority the candidate shall be summoned, on the
31st July, to defend his thesis; and finally, if the
senate think fit, he shall be admitted, on the first
lawful day of August, to the degree of doctor.

Sect. XI. The Senatus Academicus, on the day
here appointed, shall assemble at ten o'clock a.m.,
for the purpose of conferring the degree; and no
candidate, unless a sufficient reason be assigned,
shall absent himself, on pain of being refused his
degree for that year.

Sect. XII. Candidates for graduation shall be
required to produce evidence of their having con-
formed to those regulations which were in force at
the time they commenced their medical studies in
an university.

Candidates who commenced their university
studies before 1825 will be exempted from the
fourth year of attendance (Sect. I.) from the ad-
ditional hospital attendance (Sect. II., Art. 3.)
from the necessity of a year's study in Edinburgh
(Sect. III.,) and from any attendance on clinical
surgery, medical jurisprudence, natural history,
military surgery, practical anatomy, pathology,
and surgery distinct from anatomy.

Those who commenced between 1825 and 1831

will be exempted from attendance on general pathology, and also on surgery distinct from anatomy.

Those who commenced between 1825 and 1833 will be required to attend only two of the following classes, viz.:—clinical surgery, medical jurisprudence, natural history, military surgery, practical anatomy.

And those who commenced before 1833 will be exempted from the attendance specified in Sect. II. Arts. 4 and 5.

N.B.—The attendance on Midwifery in an university (Sect. II., Art. 1,) is required of all candidates.

REGULATIONS OF THE ARMY MEDICAL SERVICE.

Candidates for the medical department of the army are required to produce the diploma of either of the Colleges of Surgeons of London, Edinburgh, or Dublin, and the following testimonials :—

Eighteen months' attendance at an hospital of celebrity, where the average number of in-patients is not less than one hundred ; twenty-four months' anatomy ; twelve months' practical anatomy ; twelve months' surgery, or (what is preferred) six months' surgery, and six months' military surgery; eight months' clinical surgery, a complete course of two or three lectures during the week ; twelve months' practice of physic, or six months' practice of physic and six of general pathology ; eight months' clinical lectures on ditto, the same as required in surgery ; twelve months' chemistry ; six months' practical chemistry ; three months' botany ; four months' materia medica ; three months' practical pharmacy, or apprenticeship ; five months' natural history ; five months' midwifery ; five months' natural philosophy.

2nd. The candidates must be unmarried, not beyond twenty-six years of age, nor under twenty-one years.

3rd. Candidates who have had an university education, and have the degree of A.B or A.M., as well as that of M.D., will be preferred, but a liberal education, and a competent knowledge of the Latin and Greek languages, are indispensably requisite in every candidate.

4th. The greater the attainments of the candidates in various branches of science, in addition to competent professional knowledge, the more eligible will they subsequently be deemed for promotion in the service ; for selections to fill vacancies will be guided more by reference to such acquirements than to mere seniority.

5th. The rank of physician to the forces, or assistant-inspector of hospitals, requires, in addition to the knowledge and experience to be gained in the regular progress of study and experience in the service, that the individual should be a fellow or licentiate of the Royal College of Physicians of London, or a graduate of the University of Oxford, Cambridge, Edinburgh, Dublin, Glasgow, Aberdeen, London, or of the Faculty of Medicine of Glasgow.

6th. Although the British schools are specified, it is to be understood that candidates who have received regular education in approved foreign universities or schools will be admitted to examination.

7th. With the exception of practice of physic and clinical medicine by one teacher, candidates must have attended separate lecturers for each branch of science.

8th. Before promotion from the rank of assistant-surgeon to any higher rank, every gentleman must be prepared for such other examination as may be ordered before a board of medical officers.

9th. Diplomas, tickets of attendance on lectures, and certificates of regular attendance by each professor or lecturer, must be lodged at this office for examination and registry at least one week before the candidate appears for examination, and likewise certificates of moral conduct and character, one of them by a clergyman, and that of the parochial minister is desirable. Baptismal certificates are required at the same time ; if the parish register cannot be resorted to, an affidavit from one of the parents, or some person who can attest the fact will be accepted.

10th. The certificate of the teacher of practical anatomy must state the number of subjects or parts dissected by the pupil.

11th. Certificates of lectures and attendance must be from physicians or surgeons of the recognised colleges of physicians and surgeons in the United Kingdom, or of foreign universities.

Note.—All communications to be forwarded "unsealed" under cover, to "The Right Honourable the Secretary of War," with the words "army medical department" at the corner.

REGULATIONS OF THE EAST INDIA MEDICAL SERVICE.

Age.—The assistant-surgeon must not be under twenty-two years, in proof of which he must produce an extract from the register of the parish in which he was born, or his own declaration, and other certificates, agreeably to forms to be obtained in the Office for Cadets and Assistant-Surgeons, Military Department, East India House.

Qualification in Surgery.—The assistant surgeon, upon receiving a nomination, will be furnished with a letter to the Court of Examiners of the Royal College of Surgeons, to be examined in surgery, and their certificate will be deemed a satisfactory testimonial of his qualification ; but should the assistant-surgeon be previously in possession of a diploma from the Royal College of Surgeons of London, or of the Colleges of Surgeons of Dublin or Edinburgh, or of the College and University of Glasgow, or of the Faculty of Physicians and Surgeons of Glasgow, either of them will be deemed satisfactory as to his knowledge of surgery, without any further examination. He is also required to produce a certificate from the cupper of a public hospital in London of having acquired, and being capable of practising with proper dexterity, the art of cupping.

Qualification in Physic.—The assistant-surgeon will also be required to pass an examination by the company's examining physician in the practice of physic, in which examination will be included as much anatomy and physiology as is necessary for understanding the causes and treatment of internal diseases, as well as the art of prescribing and compounding medicines ; and Dr. Hume will then require him to produce satisfactory proof of his having attended at least two courses of lectures on the practice of physic ; and, above all, that he should produce a certificate of having attended diligently the practice of the physicians at some general hospital in London for six months ; or at some general hospital in the country (within the United Kingdom) for six months, provided such provincial hospital contain at least, on an average, one hundred in-patients, and have attached to it a regular establishment of physicians, as well as surgeons. No attendance on the practice of a physician at any dispensary will be admitted.

The assistant-surgeon is also required, as a condition to his appointment, to subscribe to the Military or Medical Retiring Fund at his respective presidency, and also to the Military Orphan Society, if appointed to Bengal.

The assistant surgeon is required, by resolution of court of the 21st May, 1828, to apply at the Office for Cadets and Assistant-Surgeons for his orders for embarkation, and actually proceed under such orders within three months from the date of being passed and sworn before the committee for passing military appointments ; he will then be furnished with an order to obtain the certificate of his appointment, signed by the secretary, for which he will pay a fee of £5 in the secretary's office.

General Cautions.—1st. Notice is hereby given, that should it be discovered at the time the assistant-surgeon is appointed, or at any subsequent period, that his appointment has been obtained by purchase, or agreement to pay any pecuniary or valuable consideration whatsoever, either directly or indirectly, when the appointment is completed, the assistant-surgeon will not only be dismissed and rendered ineligible to hold any situation in the East India Company's service, under the court's resolution of the 9th August, 1809, but all the parties concerned in procuring the appointment surreptitiously, or in disposing of or receiving the same under such circumstances, will subject themselves individually and collectively to a criminal prosecution for a misdemeanor, under the Act of the 49th of George the Third, cap. 126 ; and the court of directors of the East India Company do hereby declare, that they will prosecute any person or persons who shall hereafter be detected in such illicit traffic.

2d. The assistant-surgeons are desired to present themselves to Mr. T. R. Clarke, clerk for passing cadets and assistant-surgeons, at the East India House, with their certificates, properly filled up and signed, by ten o'clock in the morning, or as soon after as possible, in order that they may have their nominations prepared against the committee meet, or the nominating director arrives—in failure of which they may have to wait for several hours, or to come another day.

If an assistant-surgeon produces a false certificate, or the dates are found to have been altered for the purpose of making him appear to be of a proper age, he is rendered ineligible to hold any situation in the company's service.

IN ADDITION TO THE PROVINCIAL SCHOOLS GIVEN LAST WEEK WE HAVE BEEN SENT THE FOLLOWING FURTHER ANNOUNCEMENTS.

LIVERPOOL ROYAL INSTITUTION.—*Anatomy, Physiology, and Pathology,* Mr. Long.—*Anatomical Demonstrations,* Mr. A. Higginson.—*Chemistry and Pharmacy,* Dr. Brett, F. L. S.—*Materia Medica and Therapeutics,* Dr. Duncan.—*Principles and Practice of Medicine,* Dr. Scott.—*Principles and Practice of Surgery,* Mr. Banner.—*Midwifery and Diseases of Women and Children,* Dr. Malins.

MARISCHAL COLLEGE AND UNIVERSITY OF ABERDEEN.—FACULTY OF MEDICINE.—*Anatomy* (*Elementary and Advanced Courses,* Dr. A. J. Lizars.—*Chemistry,* Dr. Clark.—*Materia Medica,* Dr. Henderson.—*Institutes of Medicine,* Dr. Harvey.—*Practice of Medicine,* Dr. Macrobin.—*Surgery,* Dr. Pirrie.—*Midwifery,* Dr. Dyce.—*Medical Jurisprudence,* Dr. Ogston.—Hospital Practice—Daily at 12 o'clock.—The Infirmary contains upwards of 200 beds ; and Clinical Lectures on Medicine and Surgery are regularly delivered by the Medical Officers.

ROYAL COLLEGE OF SURGEONS IN IRELAND. *Anatomy and Physiology,* Dr. Jacob.—*Descriptive Anatomy,* Dr. Hargrave, and Dr. Hart.—*Surgery,* Dr. Wilmot, and Dr. Porter.—*Practice of Medicine,* Dr. Benson and Dr. Evanson.—*Chemistry,* Dr. Apjohn.—*Materia Medica,* Mr. Williams.—*Midwifery and Diseases of Women and Children,* Dr. Beatty.—*Medical Jurisprudence,* Dr. Geoghegan.—*Hygiene,* Dr. Maunsell.—*Botany,* Dr. Bellingham.—*Natural Philosophy,* Dr. Apjohn.—*Comparative Anatomy.*—Dr. Jacob.

ROYAL COLLEGE OF SURGEONS, EDINBURGH.—*Natural Philosophy,* George Lees, A.M., and Mr. Glover.—*Anatomy and Physiology,* Dr. Lonsdale and Dr. Mercer.—*Practical Anatomy,* Dr. Mercer and Dr. Lonsdale.—*Anatomical Demonstrations,* Dr. Mercer and Dr Lonsdale.—*General Anatomy and Physiology,* Dr. Knox.—*Chemistry,* Dr. Fyfe and Dr. Reid. — *Practical Chemistry,* (Three Months' Courses) Dr. Fyfe and Dr. Reid.—*Materia Medica,* Dr. Seller and Dr. Douglas Maclagan.—*Practice of Physic and Pathology,* Dr. Craigie and Dr. Alexander Wood.—*Clinical Medicine* (Mondays, Wednesdays and Fridays,) Dr. Craigie.—*Surgery,* Dr. J. A. Robertson, Dr. Handyside and Dr. J. Duncan.—*Clinical Surgery,* (Tuesdays and Thursdays,) Dr. Handyside.—*Midwifery,* (Three Months' Courses,) Dr. W. Campbell, Dr. Marr and Dr. Moir.—*Forensic Medicine,* (Monday, Wednesdays, and Fridays.) Dr. Skae and Dr. Cormack.

We are glad to hear that Dr. Conolly, of Hanwell, the success of whose benevolent, and at one time thought, chimerical efforts, give him so many claims on the gratitude of the philanthropist is about to publish a work on the best mode of treating the insane.

The Court of Appeal has confirmed the decision of the Superior Court at Marseilles, excepting the prescriptions of physicians from the operation of the recent law of weights and measures.

[H]ymnus poeticus Suae Majestatis Victoriæ, Augustissimæ Magnæ Britanniæ Reginæ, dignissimoque regio illius conjugi Principi Alberto, celebrando felicum conservationes salutem, Dei trigesimi, Maji, 1842, *Sacrutus*, London: M'Gowan & Co. (Feldmann, M.D. Autore.)

"As good almost kill a man as kill a good [bo]ok," and not by a damning silence to be ac[c]essory before the fact to the assassination of [re]ally one of the *best* books of its kind it has [ne]ver been our happy lot to poke our nose [i]nto, we take the liberty of acting towards it [i]*n loco parentis*, and introducing the hopeful [p]rogeny of the German *savant* to the hearts [a]nd affections (need we add protection?) [o]f the society frequented by the MEDICAL TIMES.

Besides this general ground however, for [n]oticing a book, which under ordinary circum[s]tances, would be beyond the pale of our ju[r]isdiction; we may further claim the privilege [o]n the principle that "Nihil *medici* a nobis [a]lienum est," and certainly the *nihil* cannot be *alienum* to us, which from the brilliant coruscations of wit and the stupendous conflagration of genius, exemplified by one of our own brethren, tends to cast a halo of redeeming glory round the whole of that unfortunate profession so long adumbrated by the deep obscurity of the Bœotia in Lincolns-Inn-fields, or the deeper darkness of the stygian pool in Blackfriars. Ever has it been our sacred pleasure to foster the talent which adds to our professional dignity and if need be to drag by a gentle force into the bright day of public administration, the shrinking genius which *born for* the world (if not *by* it) would possibly for ever waste its sweetness without our notice, in an obscure corner on a bookseller's shelf, or probably, less vagrant still, wrap itself up like a hibernating mouse in the contracted foldings of its own modesty, and there sleep out the long winter of its glorious discontent.

Let the disparaging critics be ashamed and flee, who say that Medicine and Parnassus are not akin—that professional latin is more canine than classical. We have had in former days an Armstrong, an Akenside, a Darwin and a Frascatorius; we have now a Wakley who composes English verses by the mile; and a Feldmann who writes Latin dithyrambics to a measure defying all powers of human calculation—prosodial or arithmetical—Yes, a Feldmann lives, and with him a Wakley, and if the ancient poets of our craft have any impudent notion of superiority, we should be glad to be favoured by a descent, to cast up accounts with them, and get them obligingly to hand over to us the balance!

The events described in this poem took place on the 30th of May last, when some miserable urchin who had heard from some Chartist orator that he paid for the Queen, had a "pop at her" with as much nonchalance as he would at a ringdove *us* duly paid for at Chalk Farm. It *appears* to be a congratulatory hymn dedicated to her Majesty and the Prince, on their escaping on that occasion any necessity for the doctor's professional services—a proof we consider, of no mean disinterestedness. We said the poem *appears* to be a congratulatory hymn, because,—and herein perhaps lies the merit of the composition,—from the peculiar syntactical arrangement of the Latin which our poet adopts in his title page we cannot quite grasp the whole of his, no doubt, vastly comprehensive idea. We speak not in complaint of this obscurity of style and thought, which, (avoiding the "assnitur pannus" of Horace) pervades the whole Epic with wonderful uniformity; it doubtless originated in the greatness of the subject. If our poet is obscure, so were the immortal Lycophron, and Apollo himself at Delphos "id est" when like Dr. Feldmann *at home*. Where such obscurity exists, the fault is in ourselves. We belong not to those envious critical dwarfs, who would oblige the great poet to reduce himself and to become as one of those little ones. If the toad with all its puffing is unable to emulate the hugeness of the bull, neither can the bull by any process of starvation or magic lose its nobility and dwindle to the littleness of the toad.

Our poetic friend, like Homer, his prototype, dashes "in medias res" with true poetic fervour: "Arma virumque cano," is not bad but the critic will be puzzled to demonstrate where *lies* its superiority to

Principis excelsæ Fasces, Sceptrumque Foemque
Britanniæ cum periculo obfuscarent! canto
Salvos Victricis Curules; quis solvet mihi
Præcepta terroris *Conjugis*; aut tumidis
Quis de montibus rapiet virides ornos?

Then follows a description of a procession to Buckingham Palace of the magnates of the land, the people, and detachments from all the nations 'from dusky Indus to the Pole.'

Jam ecce Duces magni, populi, frequensque viator
Buckingham protrudit iter:—

To use a vulgarism 'all the world and his wife,' proceed on this congratulatory visit: merry youth and hobbling age, nobility and *snobility*, including of course both the Lord Mayor (civicus prœses) and the muse Calliope (here flatteringly termed *speciosa virago*), a most *amusing* duet! while the rear is brought up by the poet himself, who (if we understand the matter) is drawn by the tumult,—pipe in one hand, and crook—or fragrant weed in the other, from his Arcadian pursuit of feeding lambs in St. James' or Hyde Park. His feelings, by a natural connection, now discharge themselves in a flood of eulogium on British hospitality, and British pre-eminence, in which are not forgotten either Nelson or Napier; Cook or *Villington*, Newton, who, according to our author, beat the Chaldeans by "extricating the deform chaos," or the *other*

Celebresque Dracones!!!
Hectoreosque duces ——
Regni celsosque Colossos, selectosque viros
Patriæque *Albertus!*—doctosque Solones!

We *feel* the beauty of this; a stupendousness booms out of the vast obscure. The "Dracones" we opine are the "Poor-Law Commissioners," with a correct allusion to their "hectoring propensities." The "selecti viri" who follow, are of course select vestrymen; among whom, however, by a poetic *deposuit superbos* is ranked "*Georgius ultimus quartus*," as the author correctly renders the *late George the IV*. By the "Solons" must be meant, we presume, the House of Lords; or, our twenty-one friends in Lincoln's-Inn-Fields.

We thus see that there is nothing commonplace in this production; the subjects chosen are most poetically incongruous—the images most original—the metaphors most bold, *e. g.*

— Occulti Potosi tremuere recessus
Inque suis fulvum foveis *perhorruit* aurum.

or this—

Sauciat abstrusæ turbans penetralia terræ
Fossor—

But we must hasten to the gem of the poem. All scholars remember Homer's catalogue of the ships; or Virgil's list of Actæon's hounds in the Georgics; the enumeration of those important personages, Glaucus, Medori, and Theilsiloehus by the former; and of Sergestas Gyas, and the brave Cloanthus, by the latter poet. How often have these been admired? Yet how pointless and inartistic their introduction, when compared with Dr. Feldmann's "catalogue raisonee" of the political celebrities of the day, with which he concludes. For the benefit of our reader, we extract the passage—

Deus Te inspirabit—*Tuis* Consiliis—
Quamquam Sagacissimus Baro Peel—Comes Aberdeen,
Nec non Palmerston, Russel, Stanley, Ripon, Graham,
Tantosque celebratos Duces, dirige, pacemque
Refer Rectoribus Orbis—Omnes *Te* adorant.
Ipseque Hume, loquax O'Connell pauperes
Patriæ defendens, gaudetque *Salum Tuum*,
Incolæ jubilatque *Magnæ Britanniæ Cor.*

We have thus far occupied our o'er wrought brain in evolving the matter of this poem; let us now look at the manner or mode of versification in which all these sublime sentiments are expressed;—not the least remarkable feature in this extraordinary production. Horace, in his ode, laudatory of Pindar, says of that bard—

Nova dithyrambos,
Verba devolvit, numerisque fertur
Lege solutis.

All this meant for the bold Theban of yore, applies with equal aptitude to the learned Theban of to-day, Dr. Feldmann, M.D. and P.F.C., We are bold to say that never, within our critical experience, did we meet with a poet whose master-mind so effectually freed itself from the trammels of prosody, and all ordinary rule of conventionalism. We note this particularly, because a less gifted, or less original mind, too timid to deviate from the beaten track, would, but too probably, have been content to have adopted, in a Latin poem, the humdrum and monotonous hexameters of which Virgil—(perhaps, unhappily, hampering his genius), constituted his Æneid. The soul of our medical son of song is too dithyrambic in its nature to submit to rule. Like the untamed eagle, he must soar with the wild grace of nature, and the magic power of perfect freedom, or he flies not at all. In this spirit he has invented, a hexameter of his own, one of peculiar construction, *e. g.*

Tales dum tractas excelsa Britanniæ Musas,
Omnibus ergo oblivisceris periculum, place
Populis, rogo, Tuis Augustissimis Prolibus,
Trementi Matri, dantque Tibi primas laudes,
Certeque, longamve vitam, palmasque Camaēnæ.

M. Feldmann, M.D. and P.F.C., with a moral hardihood that marks him out for a great social innovator, has been the first boldly to come forward to shew his supreme contempt for petty grammatical concords (see his Preface and Epilogus), and to put his hoof upon the metrical laws. How glorious and consolatory to a lover of the Juvenile race are his perpetrations of what are vulgarly called "false quantities!" How felicitous the accomodative, the creative power of his genius which makes "frequens" a spondee! and "posse quàm" a dactyl! "Nos Germâni non curâmes quantitatem," is a proverb; which wanted its climacteric illustration till Dr. Feldmann wrote; and with his potent pen decreed the everlasting destruction of the sophistical and arbitrary distinctions of syllables into long and short! Catholic emancipation will go hand in hand down to posterity, with the deliverance worked by Dr. Feldmann, for the schoolboys of England; a hint for convening a meeting of the juniors of Eton, Harrow, and Westminster, to consider the best mode of acknowledging his public services, which we trust will not be overlooked. In conclusion, we congratulate our Author upon his loyal effusion; he evidently possesses the true poetical diathesis. Like Pope, he *lisps* in verse." The secretions of his gifted mind—to speak in the language of a modern school—are evidently tinctured by no prejudice in favour of pounds, shillings, or pence; his is

one of those works which have no chance of profitable appreciation, save from that portion of the human species which follows us posteriorly: and which, if no other book were written, would alone justify Sir Robert Peel's prolongation of the period of Author's copyright: especially, if there could be any provision in the act, that the work shall be printed on paper, like that before us.

MEDICAL REFORM.

To the Editor of the 'Medical Times.'

SIR,—I have perused the judicious remarks of the experienced "Peter Anodyne," with great pleasure, and cannot refrain from expressing my entire concurrence in the opinion, that if the Apothecaries Act were fairly and fully carried out, the great body of medical practitioners would have but little to complain of.

The sale of nostrums, although a serious evil, both to the profession, and the community generally, is not so prejudicial to the interests of the former, as the host of illegal practitioners who are everywhere allowed to prey upon society. I imagine that you would be not a little surprised, accustomed as you are to view the subject, if you were to request your subscribers to transmit you a list of the number of these "quacks" infesting their own immediate neighbourhood. It would be seen, and that very conspicuously, that the Apothecaries' Company have justly forfeited all claim to the respect of its licentiates, and that they are, indeed,in another than a medical sense,men of 'art and mystery,' as they are y'cleped in their certificate.

In the small town wherein I practice, there are six practitioners, two of whom are legally unqualified. These two individuals have each a parochial district assigned to them by the Board of Guardians; and one of them in particular is favoured by the patronage of an influential person, so that it would be exceedingly difficult, if not impossible, for a duly qualified practitioner to displace him. But, this is not all, for within the present month, I was called to visit a farmer in the country, who had been attended during his illness, by not less than three unqualified persons.

Now, if such be the state of this town and neighbourhood, with respect to those who practise medicine, may it not be suspected, that a candid avowal on the part of others, in other localities, would present a corresponding state of things? And, although I hope that such is not the case, both for the sake of the profession generally, and the credit of the Apothecaries' Company in particular, I am tempted to exclaim,—ab uno disce omnes! I say nothing about prescribing and visiting druggists, although there are such in this town, as they possess only a very humble share of respect with the public, and that only among the lower grade; but I do say the irregular practitioners are worthy of attention, because they enjoy a share of confidence, sufficient in degree to enable them to carry on a very lucrative business, which is of course, just so much taken from the income of the regularly educated surgeon-apothecary.

Such are the few facts I have been led to relate, by reading the letter of "Peter Anodyne." How far he is justified in attributing the cry for reform to restlessness, produced by lack of patients, I leave others to decide. But this I may be allowed to say, that to a "grey-headed old man," who has nearly completed his course, the question of reform or no reform, must be equally unimportant. We all know how men in declining years hug established customs, and even learn to love the evils they once deprecated.

I will, in conclusion, mention a suggestion that has often occurred to my mind. If the Apothecaries' Company would set themselves to work, like honest men, having the interests of the profession at heart, to remove the abuses universally felt, and which they have the power to do, they might, by appointing a competent, travelling inspector, to visit every corner over which their jurisdiction extend, do much, very much, to remedy the present aggrieved condition of the profession.

I am, Sir,
Your obedient Servant,
A. LICENTIATE.

Sept. 27, 1842.

MEDICAL NEWS.

ALLEGED DEATH OF A LADY FROM POISON ADMINISTERED BY MISTAKE.—A few days ago a lengthened inquiry was proceeded with before Mr. Higgs, deputy coroner for the city and liberties of Westminster, at the sign of the King of Prussia, in Lower John-street, Golden-square, into the circumstances attendant upon the death of a maiden lady, named Elizabeth Campbell, aged 44 years, residing at No. 19, Golden-square, who it was alleged had died from the effects of poison. On the arrival of the coroner fifteen of the residents of Golden square, &c., were empannelled as jurors, and Mr. Austin appointed foreman, upon which they proceeded to the residence of the deceased lady to view the body, when the following evidence was adduced:—It appeared from the evidence of Ellen Joyce, the cook, and Mary Anne Mason, the housemaid, that the deceased and her sister, Miss Hannah Campbell, resided together at the house No. 19, Golden-square. The deceased had for some time been indisposed, and for several weeks had been confined to her bed; she was attended by Mr. Johnston, surgeon, of Beak-street, Regent-street, who saw the deceased on the forenoon of Friday, the 16th ult., and ordered her a table-spoonful of potash water diluted with a similar quantity of milk. Immediately after he had left, Miss Hannah Campbell asked the cook if she knew what potash water was, to which she replied in the negative, when she was desired to go to a chemist to procure the smallest quantity they would make. The cook accordingly proceeded to the shop of Messrs. Fowler and Co., chemists and druggists, No. 14, Brewer-street, and asked for a small quantity of potash water. The person whom she saw asked her what it was, but she told him she did not know; he then asked her if Miss Campbell was going to wash, but she again told him she did not know. He then told her she could have fourpennyworth, and she put a bottle she had brought with her down on the counter, and left it while she went over the way to a greengrocer's. On her return to the chemist's shop, a bottle rolled up in paper, was given to her, which, on reaching home, she gave into the hands of Miss Hannah Campbell who took it up with her to deceased's room. Miss H. Campbell then, in the presence of the housemaid, mixed a tablespoonful of the stuff with an equal quantity of milk in a glass, and gave it to the deceased, who immediately she had swallowed it, exclaimed, "You have poisoned me—I am all on fire," and she appeared in verygreat pain. Mr. Johnston was instantly sent for, but before his assistant (Mr. Keys) could arrive, the deceased had, through the agony she was in, torn all her clothes off. He arrived in about five minutes afterwards and administered to her a draught, and subsequently some drops in water. On showing him the bottle from which the stuff had been poured, he immediately said, "Oh, dear, this is not the stuff Mr. Johnston ordered," and seemed very much agitated. On leaving the house he took the bottle and the contents with him. The bottle was labelled "Potash water," and bore also a label with Messrs. Fowler and Co's. names and address on it. Miss H. Campbell afterwards told the servants that the bottle contained prussic acid. Deceased continued to get worse, until the commencement of last week, when she rallied very much, but notwithstanding died on Thursday last. Mr. Francis Johnston, the surgeon, deposed that he had attended the deceased since the 9th ult. for an attack of inflammation of the membrane covering the bowels. In consequence of the great sickness she laboured under, nothing stayed on her stomach, and witness ordered her on the 16th ult., to have some potash water, telling her sister, who was at the time at the side of her bed, that it was an effervescing beverage like soda-water, and offerred to write it down, so particular was he in his description; but Miss H. Campbell said it was not necessary. Witness then left the house, and on his return home from Peckham, about three o'clock was informed by his assistant of what had occurred, upon which he immediately went to deceased's residence, and found her in bed, every thing having been done that could be, the poison having been extracted from her stomach, and the proper antidotes were continuing to be applied. The Foreman inquired if Mr. Johnston had seen the stuff that was sent by the chemist for potash water? The witness replied that he had. He then produced an ounce phial, containing a deep yellow liquid, and said the contents was a caustic preparation of potash, of a burning and poisonous nature, and was only used medicinally by drops in a diluted state. Witness had since learned to his surprise, that it was frequently sold by chemists for potash-water. The witness then produced a bottle of the real potash-water, as purchased at the shop of Messrs. Savory and Moore, the well-known chemists of Bond- treet, which completely resembled both in colour and appearance a bottle of soda-water. Examination resumed: At the time the deceased swallowed the stuff she had a dozen leeches on to lessen the inflammatory symptoms, but they became very much increased, and she got gradually worse, until, on the 21st ult., when witness expressed his fears very strongly to her sister, and advised her to have further advice, Mr. Copeland of Golden-square, and Dr. M'Leod, were accordingly called in, who recommended a continuance of the same medicines witness had prescribed, and Dr. M'Leod, continued in attendance until Monday last, when it was anticipated the deceased would recover. She apparently continued to improve until about four o'clock on Thursday morning, when a change took place and she died on the same day. Had since made a post mortem examination of the body, and had found, on examining the stomach, evidence of very extensive and old disease. There were two large sists and a mass of disease generally. The stomach was redder than usual, being ecchymosied in the texture. Witness had also tested the contents. Although he had then found sufficient to account for deceased's death, he opened the head and found a clot of blood in the brain, and, in witness's opinion, she died from apoplexy. The foreman inquired of the witness if that, in his opinion, had been caused by the effect of the poison she had taken? Witness said it was impossible to say, but from the effect she described it had upon her, as of her head going through the ceiling, it might have accelerated her death. The clot was about the size of a nut, and there was also effusion of serum. The sist he had described was an immense one, the slightest pressure on which might have caused apoplexy.—By the Foreman and Jury: The potash contained in the bottle produced, was what is called "liquori potasiæ." A table-spoonful on an empty stomach would act as caustic and produce inflammation, but certainly, mixed with milk, it would be less powerful. It was generally used in bleaching, and was quite different to potash water. The latter was not kept by general practitioners, but was sold by chemists. Could not say that deceased's death had been produced by her having swallowed the potash. Had witness sent out that kind of potash he would have labelled it "Potash liquor—poison." Did not think when he ordered the deceased potash water, that it was necessary to write it down, any more than he should had he ordered her ginger-beer. As a surgeon he would not have sold that kind of potash at all, unless it was diluted.—Mr. Fowler was then sent for, and having been cautioned by the coroner not to say anything likely to criminate himself, said he was in the shop at the time the cook applied for a small quantity of potash water. He asked her what it was for, but she said she did not know. She brought no bottle for it, and having again asked her if it was for cleaning paint, she replied in the negative; and although she said it was for Miss Campbell, she did not say that lady was very ill, neither did she ask for "effervescing" potash water. That kind of potash being much used for cleaning marble or taking out grease, he thought it was required for something of the kind, as she asked for only a small quantity, and gave her the ounce bottle produced, which was the smallest quantity they sold.—By the Jury: Did not think sending the bottle without labelling it "poison," was rather a loose way of carrying on business, as there was nothing deleterious in it. If the whole had been taken, it might probably destroy life. Was in the habit of selling the effervescing potash water, but called aerated potash water. Never knew an article like that marked poison, although

that quantity would destroy life. Had labelled it the same way hundreds of times; all chemists did the same.—The jury said they thought Mr. Fowler had not taken proper precautions to ascertain the object for which the potash water was wanted, and at their request the coroner ordered the inquest-room to be cleared.—After the lapse of an hour the public were re-admitted, and—The Coroner said the jury had returned the following verdict: —"We find that the deceased died from apoplexy, accelerated by taking a spoonful of caustic potash water, instead of effervescing potash water, ordered by her medical attendant. The jury cannot but regret that the medical man omitted to write his prescription; and feel a strong conviction of the impropriety of the chemist selling deleterious liquids without a distinct label of 'Poison' thereon."

No. 160. Vol. VII. LONDON, SATURDAY, OCTOBER 15, 1842. PRICE FOURPENCE. STAMPED EDITION, 5D.

For the convenience of Subscribers in remote places, the Weekly Numbers are re-issued in Monthly Parts, stitched in a Wrapper, and forwarded with the Magazines.—Orders for the Stamped Edition [10s. 10d. per Half-year, Post-free in advance,] are received by any Bookseller or Newsman, or may be directed to J. A. Carfrae, Esq., at the Medical Times Office, (late Lancet Office), London.

SUMMARY.

LECTURES ON THE ANATOMY AND PHYSIOLOGY OF THE NERVOUS SYSTEM.

By Professor OWEN, F.R.S., &c.

The transition from the class of fishes to that of reptiles, is evidently made by the lepidosiron, a true fish, according to its scales, its semi-cartilaginous semi-osseous skeleton, its double superior and inferior spines, its spiral intestinal valve, its heart and olfactory organs,—but presenting, among fishes, the closest approximation to reptiles, in the development of the cerebral hemisphere, though inferior, as was said in the previous lecture, in the development of its cerebellum, to the vigorous and locomotive shark. In many respects, as in the vermiform figure of this singular fish, and in the almost abortive condition of its locomotive members, where we see the fin of the true fish reduced to a single-jointed soft ray, there is an evident degradation of the type, preparatory to its assuming that of the higher class. To use a figurative expression, Nature would seem here to take a step back, before springing to higher vantage ground.

The lowest organized of the true reptiles—in their general form and the low condition of their locomotive organs, in their combination, also, of lungs and gills, their lungs resembling the cellular air-bladder of the lepidosteus—more closely resemble the sauroid, than they do the higher-organized selacian fishes. These form the order of reptilia perenni-branchiata.

Another low-organized order, which manifest branchiæ, in combination with lungs only at the earlier period of their existence, as the toads, frogs, and salamanders, are called caduce-branchiata.

The order of Ophidians, so called from the Greek word, *Ophis*, includes all the various tribes of venemous and non-venemous serpents.

The Chelonian order includes the turtles, terapins, and tortoises.

The Lacertian includes all the four-footed lizard-like reptiles which are covered with scales, have simple ribs, and a double penis.

The Crocodilians, which are the highest-organized reptiles, are represented, at the present time, by comparatively few species of the largest of the lizard-like animals, called alligators and crocodiles, and which have their anterior ribs provided with a double head, which have a single intromittent organ, and are the only reptiles resembling the warm-blooded class, in having the ventricles, as well as the auricles, completely divided, and, consequently, a four-chambered heart.

In the reptilian class of vertebrated animals, notwithstanding the very great diversity of external form the cerebro-spinal system presents less variety than in the class of fishes. There is always a greater predominance of the central masses, and especially of those which take no share in the origin of nerves. In the lowest organized reptiles, we find the medulla oblongata more simple, and smaller than in fishes, presenting a large and widely-open fourth ventricle, not more protected by a cerebellum than in the mixinoid fishes. Such is its condition in the syren, the menobranchus, the frog, and the toad. In Ophidians, the cerebellum is of large size, but still inadequate to cover the 4th ventricle. Still smaller than most fishes, the Lacertian reptiles present another step in the development of the cerebellum; but here it is relatively smaller than in the crocodile or turtle, and in neither of these reptiles is it superior in size to the osseous fishes. In no reptile does it present convolutions as in the shark; yet, compared with the cold and vegetative condition of the procreative function in osseous fishes, to which the coitus is denied, the ardour of the sexual impulse in snakes and lizards, which are superior to all other creatures in the physical conditions for the full enjoyment of the act, present a marvellous contrast: with which the condition of the cerebellum, in the hypothesis of Gall, might have been expected to present some relation in its development. How its absolute, as well as relative inferiority in size, is to be reconciled with so marked an advance in the function over which it has been supposed to preside, it is for phrenology to determine. The cold-blooded, air-breathing, vertebrated animals are, however, sluggish to a proverb, and few there are that do not pass a considerable period of their existence in inactive torpidity. In none of these do we perceive any approach to the restless, ever-changing rapidity of course, often to be compared to an arrow darting from the bow, which the finny tribe present to view, and which powers arrive at their maximum in the shark. It would seem, therefore, rather to the low condition of the locomotive energies in reptiles, that the small size and great simplicity of their cerebellum is to be connected.

The optic lobes, which are the next masses of the brain met with, tracing them from behind, forwards, in the class of reptiles, are in the perenne-branchiata species, likewise, of much smaller relative size, than in fishes. They are also single, and vesicular, as in the early embryonic stages of the birds and mammals. They are double, and of larger relative size in serpents and in lizards; still larger in crocodiles; and largest of all in the turtle; but are always smaller than the cerebral hemispheres. They are implanted, as it were, on the anterior prolongation of the medulla spinalis; are double; are united together by a raphe; and are most distinct behind. They always contain ventricles, which communicate together and with the third ventricle below, on which they rest. The pia-mater lining these ventricles, is very vascular; the optic nerve arises by two roots, one from the upper and inner, the other from the lower and outer part of each tubercle.

As we have hitherto seen the cerebellum rise and fall, as it were, with the corresponding exaltation or depression of the muscular masses, so the optic lobes, in their varying development, present a similar correlation with the varying conditions of the visual organs. They are large, for example, in most fishes, in which the outward organ of the sense of sight is of great size. The diminution of the optic lobes, corresponds, in the lower Batrachians, with the rudimental condition of the eyes in these creatures. The resumption, by the optic lobes, of their former proportions in the lower class, is coincident, in reptiles, with the progressive development of the organs of sight, and culminates in the turtle, which have the largest eyes in the class of reptiles.

It is highly remarkable, and furnishes much ground for reflection, to observe the constant preponderance of size of the cerebral hemisphere over all the other parts of the brain, in all orders of reptiles. The cerebral hemispheres are long, and larger than the optic lobes in the Batrachian and Ophian reptiles; they increase in breadth in the peaceful herbivorous tortoises and turtles; acquire their greatest breadth in the crocodile, which is, however, not more combative or destructive than the carnivorous, sabre-toothed, varanus lizard. The base, or posterior part of the hemisphere, hardly reaches the optic lobes in the lower Batrachians, but does so in the higher reptiles. The apex or anterior part of the hemisphere, is prolonged into a hollow canal, and sometimes swells into a small olfactory ganglion. The hemispheres are distinct from each other anteriorly, but are united posteriorly by a commissare, like the soft commissare. They are hollow, the inner surface of the ventricle is highly vascular; its walls are thin; at the anterior and inferior part of the ventricle, there is a small eminence. These ventricles communicate with the third ventricle, which passes downwards to the infundibulum, and upwards to a vascular, pineal canal, the walls of which are not thickened by glandular matter.

The relative weight of the brain to the body does not bear any ratio to its state of development, but is chiefly influenced by the bulk and weight of the species. Thus, in the light and slender lizard, the weight of the brain to that of the body, is as 1 to 160, whilst in the crocodile, which has, unquestionably, a much better developed brain, it is as 1 to 8000.

With regard to the habits of reptiles, and to the distinct and energetic manifestation of these as elements for testing the possible relationship of any particular portion of the supra-ventricular masses, called organs in phrenology, with such manifestations, we have to observe, that so far as is known, the instincts, appetites, and physical phenomena of reptiles are few, simple, and well marked; as a general rule, reptiles are carnivorous, and take their food alive. Certain tortoises and turtles, the iquanos amongst lizards, are herbivorous. Some of the carnivorous lizards chase their prey. The common green lizard may be said to be astute. The chlamydosaurus, and some more common sorts of lizard, threaten and offer battle when alarmed. It is not in the outer or lateral parts of the cerebral hemisphere in the predatory and combative lizard, that we find the corresponding developments. Their brains are much narrower than in the timid turtles.

All reptiles swallow their food gluttonously. Some live together, but there are no regularly organised communities. No reptile manifests any care or fondness for its offspring, unless, indeed, the vague tales of the viper swallowing its brood and disgorging them unhurt when the danger is past, be true. At any rate, the film of cerebral matter, forming the posterior wall of the cerebral ventricle, is relatively as thin in the viper, as in the crocodile, which is stated to watch the shores on which its eggs have been deposited, allured by the blind instinct of preying on its newly hatched progeny. Whether the very low development of the part of the brain, to which the maternal instinct, in regard to the care of her offspring, has been supposed to reside, relate to the almost complete absence of that instinct in the crocodile and other reptiles, we shall, perhaps, be able to determine, by examining the condition of the so called philo-progenitive organ to the class of birds.

Symptoms caused by Cantharides.—An attempt to poison was lately made at Evran (Ile et Vilaine), on two young girls, one aged 22, the other 14, servants to an innkeeper of that town. A tinker named N., who occupied a room near that of the two girls, mixed with their food some powder of cantharides, doubtless hoping to accomplish some abominable design, aided by the properties attributed to this powder; but the violent colics which supervened, soon disclosed the culpable project of N., who has been committed to the prison of Dinan.

A LECTURE INTRODUCTORY TO A COURSE OF ANATOMY AND PHYSIOLOGY.

By ROBERT HUNTER, MD., Lecturer on Anatomy and Physiology, Westminster Hospital Medical School.

Gentlemen,—In the ensuing course of lectures it will be my sincere and anxious endeavour, in conjunction with my respected colleague, to lead you into a knowledge of the art and science of anatomy. The term anatomy, as you probably all know, literally means dissection—a term that refers rather to one of the modes of investigating the science than to the nature of the science itself. But the term anatomy in this literal and restricted signification, expresses very imperfectly the importance of the subject we are about to investigate. Anatomy is properly the science of organization, and how many topics of overwhelming interest and deep study does the word *organization* imply! The world we inhabit may be said to consist of two kinds of matter only, that which is called unorganized or dead matter, and that in which a vital force, a principle of vitality, exists, and from the complexity or peculiar arrangement of its component elements, takes the name of organized matter. Organized beings then form one of the two grand divisions into which all material existences may be arranged. The science of organization is thus necessarily of great extent, for it includes the whole domain of animated nature. It leads to a knowledge of the component parts and intimate structure of all living beings, vegetable as well as animal—it conduces to scientific and just principles of classification among these beings—it gives an insight into the causes of the varied operations external and internal—mental and instinctive—as well as corporeal, which such beings display. It throws a blaze of light upon the nature and treatment of diseases incident to organized structures, and has even been made the stupendous instrument of determining the successive changes to which "the great globe itself" has been subjected since its first formation.

Although the structure and organization of man as a branch of medical study will chiefly occupy our attention in the ensuing course, still our investigations will necessarily take a wide and very extensive range. The structure of man cannot be fully or satisfactorily illustrated by investigations exclusively confined to the human structure. This remark may appear paradoxical, but it is, nevertheless perfectly just, for many of the organs of which man is composed, exist in a higher state of development in some of the inferior animals than in man, and it is only where the organs are found in the highest structural perfection, that their uses and importance in the animal economy can be fully recognised or appreciated. It is obvious, therefore, that in investigating the structure of man we must necessarily refer to the structure of other animals, and our deductions from this source will be neither few nor unimportant. The structure of man, besides, includes all the varied and remarkable changes that take place, from the almost inappreciable atom by which he commences his career of existence till he has attained the full measure of his development. But these conditions, which are fleeting and evanescent in man, are fixed and permanently stamped in the various kinds of inferior animals; so that by studying the modifications of structure as found in these animals, we study, and that under favourable circumstances, the changes of form and structure incidental to human development.

That you may be enabled to form some idea of the subject we are about to investigate, I shall place before you a brief outline of the principal topics that will occupy our attention in the ensuing course. In studying anatomy the pupil is too apt to be contented with a knowledge of the *descriptive* anatomy of the human body. If he can enumerate the bones and all their processes, if he can tell the origin, insertion and uses of all the muscles—if he can name the blood-vessels and their principal branches, and haply condescend upon the relative situation of those vessels concerned in the capital operations of surgery—if he can describe the situation of the viscera, and comprehend the structure of the organs of sensation,—he is too apt to conceive that his knowledge of anatomy is completed. But, however indispensable all this knowledge may be, it constitutes but a small part of the science of organization. That science takes cognizance of all the primary *tissues* or textures that enter into the formation of organized bodies—*the combination of these textures* into organs, by the assemblage of which an animal body is formed—the physical and physiological properties, and relative situation of these organs—the modifications of structure that exist in the organs of different animals—the changes of structure which the organs undergo during the process of development, and lastly the principle on which all animal bodies are formed and developed.

The science of organization takes cognizance, as I have already hinted, of vegetable as well as animal structure, and these two kinds of living matter do not differ so much as might at first view be imagined. The vegetable tribes display organs and functions that will bear comparison with the corresponding organs and functions of the animal part of the creation. If in vegetables the organs are less developed, a greater development is not required, as these beings are fixed to the soil on which they subsist, whereas the animal tribes are so constituted that they must seek for nourishment which is often at a distance, and consequently must have powers and capacities for searching it out, for distinguishing it from what is innutritious or baneful, and for appropriating it when found to the wants and exigencies of their systems. We shall confine ourselves in this course to *animal* organization, and from what has been already stated you can form some idea of the extensive nature of the subject, into the investigation of which you are about to enter. So important, indeed, is even this restricted subdivision of anatomy viewed, that it has been still farther divided into distinct branches, and these treated as independent subjects of scientific pursuit. Thus we speak of anatomy as general and special, human and comparative, descriptive and surgical, normal and pathological, and philosophical or transcendental. Although all these branches, to a greater or less extent, are included in the anatomical department of every well conducted medical school, yet in this, and other schools, it has been found convenient to investigate the subject under a two-fold aspect—that of practical and that of theoretical anatomy, or under the less objectionable titles of descriptive and of general anatomy, a course of prelections being devoted to each department.

The descriptive and practical course will be found to embrace the following most useful and indispensable branches of study:—1st. A minute description of all the parts of the human body, or what may be denominated descriptive human anatomy in all its details: 2nd., relative, regional, or surgical anatomy, or the relation which the parts previously described bear to each other in position and in reference to the operations of surgery; and 3rdly, practical anatomy, or the method of investigating the structure of the human body by dissection. On these subjects it is unnecesary at present to dwell, as my respected colleague at the appointed time will commence this important division of our subject, and bring the matter fully under your observation.

The subject which falls to be discussed at this hour of lecture, will be found to be of a deeply interesting and philosophic character; for it will combine both anatomy and physiology; and the anatomy introduced and discussed at this hour will be of a different kind—of a more general nature—referring more to intimate structure than that given at the hour of demonstration. The anatomy which we shall introduce to your notice at this hour, will have a special view, I had almost said a constant reference, to physiology. So much, indeed, will anatomy and physiology be carried hand in hand in this course that we might designate the course as one of physiological anatomy. You all know the difference between anatomy and physiology; you know that anatomy has a reference only to structure and physiology to function; that anatomy is the science of organic structure and physiology the science of organic action or function. The line of distinction between these two kindred departments of science is thus easily drawn, but the relationship is, notwithstanding, so close and intimate between them, that we can hardly suppose the one science existing without the other, and most assuredly you will find that they can be investigated most easily, pleasantly, and effectually in conjunction and in combination.

In this course the physiology will hold a prominent part, and what science can be named that comprehends so many fascinating subjects of inquiry as physiology? We contemplate with a sublime pleasure the working of a machine like the steam engine, but in the operations of an animal body there is more to admire than in all the complicated movements of that transcendant effort of human genius. A steam engine is nothing more than a philosophical and happy combination of mechanical powers; but although there is much in an animal that is purely mechanical, there is also something that mechanics alone cannot explain. The human body is, no doubt, a machine of exquisite mechanical structure, but it is also a *living* machine, and the vital properties of its various tissues and combinations of tissues lead to loftier and more refined investigations than those to which mechanical science conduce. Can we look with apathy at an inferior animal waking from its sleep, springing as it were into new existence, exhibiting locomotive powers as if under the influence of magic, revelling in the full enjoyment of all its senses and displaying the other attributes of its nature? Or contemplating the extraordinary capabilities of man, who, besides displaying those powers that arrest attention in the inferior animals ,exhibits likewise those sublime, I had almost said incomprehensible, moral, and intellectual endowments which raise him so far above every other animal, and fit him for purer pleasures and a higher destiny? Can we contemplate these capabilities, I say, or come to the investigation of such sublime mysteries without emotion? Man is physiologically a living miracle of nature, and were he not so frequently before our eyes would be viewed as the most astonishing of things.

As this course will embrace anatomy as well as physiology, and as anatomy or structure necessarily lies at the root of all physiological enquiry, as it is the point from which this enquiry must proceed and to which it must return, we shall be thus led to an extended survey of animal structure and organization, a survey which may be said to comprehend the five following subjects of anatomical study:—1st. General anatomy, or the anatomy of the primary tissues of the body.—2nd. Special anatomy, or the anatomy of the organs and systems of organs formed by the union and combination of the primary tissues.—3rd. Comparative anatomy, or the peculiarities of structure which exist in the corresponding organs of different animals or groups of animals as compared with the human organs.—4th. Developmental anatomy, or the investigation of the changes which each and all of the organs undergo from their earliest formation to their full growth: and lastly, philosophical or transcendental anatomy, or the investigation of the fundamental type or model upon which animals and their various organs are formed. Permit me to make a few remarks upon each of these topics.

1. *Of General Anatomy.*—This appellation is usually given, as I have already hinted, to that department of science that treats of the primary or elementary *tissues* that enter into the formation of the more complicated parts of an animal body. Every part of the body is more or less of a complicated structure. In the *skin*, for example, besides the three fundamental layers, the cutis, the rete mucosum and the epidermis, we find a numerous assemblage of arteries, veins, lymphatics, nerves, sebaceous follicles and hairs, all united in a determinate manner, by cellular membrane, so as to form a sensitive and protecting envelope for the whole body. In this simple-like membrane, then, we have a great complexity of structure, and in some organs, as the eye and its appendages, all the textures of the body are congregated. The object of general anatomy is to unfold and display these textures in their simple and uncombined state and to ascertain their peculiar physical and physiological properties. To Bichat we are indebted for the first satisfactorily systematic and full

description of these textures and, such was the ability he brought to the undertaking, that notwithstanding the eminent men that have followed him in the same track of investigation, it may be justly questioned if any important additions to general anatomy have been made since the time of Bichât.

The primary textures of the human body, according to this authority, are twenty-one in number, and that they may be the more easily comprehended, we shall arrange them into two classes. First, the generally diffused textures; and, secondly, the *particular tissues*, or those found in determinate parts only of the body. In the first, are included the cellular, the nervous, the arterial, the venous, the exhalent and absorbent tissues; and the second includes tissues of the following denominations: the osseous, the medullary, the cartilaginous, the fibrous, the fibro-cartilaginous, the muscular, the mucous, serous, synovial, glandular, dermoid, epidermoid and pilous. The import of these terms, we cannot wait, at present, to explain, far less to enter upon a description of the tissues themselves; we may, however, be permitted to say, that the generally diffused tissues, as the name implies, are found, in a greater or less degree, in every part of the body, so that could we insulate completely any one of these tissues, it would present an exact resemblance to the general form of the body from which it was taken. We might, therefore, consider the generally diffused textures, as the nidus, in which the special textures rest and are incorporated, or we may view the more *special* textures as so many pieces of the frame-work of the system, and the generally diffused tissues as their connecting media, and supporting and vivifying apparatus.

Of these tissues, three are viewed by many anatomists as fundamental, existing in all animals, and essentially different in their physical, chemical and physiological properties; these are the cellular, nervous and muscular. More lately, the German physioligists, Schwann and Schladen, have demonstrated, that all the textures not only originate from ulcerated cells, but that a striking similarity, if not an identity of structure, exists in the originating cells of animal and vegetable organizations.

As text-books of General Anatomy, I can recommend the Anatomie Generale of Bichât, an original work of transcendant ability; also, the Elements of General Anatomy, by Beclard, translated and edited, by Dr. Knox, which, though written with less eloquence and originality, is a superior production to the other, in the condensation of facts, and in reference to sources of information.

2. *Of Special Anatomy.*—The study of the individual organs and systems of organs which exist in any animal body can only be successfully prosecuted after some knowledge has been attained of general anatomy. Every organ consists of an assemblage of simple or primary tissues arranged in a peculiar but determinate manner; but it is obvious that our knowledge of the structure of any organ, or indeed of any compound substance, would be very imperfect if we were unacquainted with the simple ingredients by the union of which the organ or compound is formed. General anatomy embraces principles that are applicable to the whole of the animal creation, for the primary textures of all animals are alike; but special anatomy is as diversified as the species of animals that inhabit the globe. The special anatomy on which we enter in this course, is that of *man*, and from its superior importance to you, as students of medicine, will constitute a large proportion of the course.

Special human anatomy is the science that treats of the situation, form, weight, colour, and consistency as well as internal constitution and structure of every organ of the human body. The branch of science thus shortly defined, is also sometimes denominated descriptive human anatomy, a department which will be considered in all its bearings as we have already stated, in the other and demonstrative course. But the special anatomy of man, which will form a part of this course, is essentially different from the other, both in the arrangement followed, and in the object proposed. In the demonstrative course we shall follow an arrangement purely anatomical; the descriptions will be circumstantial and minute, with occasional references to the practice of surgery; but in this course we shall follow an arrangement based on *function*; our descriptions will be more general, and physiological disquisition will take the place of dry anatomical details. In conformity with this plan, we shall view all the organs, numerous though they be, of which man is composed as arranged into three classes:—First, Organs of relative life, or those organs which connect man to external narure, and which enable him to appreciate and enjoy the relationship in which he is placed. Second, organs of nutrition or organic life, or those organs that preside over the internal, vital, or organic motions and operations of the whole system. Third, organs of reproductive life, or those which conduce to the continuance of the species. By the combined action of these organs man is formed, grows up, and displays in full vigour the powers and energies of his nature.

The organs of the first class, or those of nutritive or organic life, are numerous, and exceedingly complicated. They may be said to preside exclusively over those internal or organic changes which are in incessant operation in the living system, and on the existence of which vitality itself may be said to depend. By the combined action of external and internal causes, the constituent parts of every living organ are soon rendered useless; these decayed parts, therefore, require not only to be removed, but new particles added to supply their place. A constant series of depositions and absorptions are thus going on in every organ of the body, and at every point of every organ, and these two conditions of matter may be said to constitute the essence of vitality. When these two phenomena exist in any organized body, whether of the animal or vegetable kind, the body is alive, and when they are wanting the body is dead. As the depositions of new particles in an animal body are made from materials foreign to the body itself, and as these foreign ingredients must be changed, and changed remarkably, before they can constitute a part of a living being, it is not at all surprising that a numerous assemblage of organs should exist for effecting such change. Time will not permit me at present to enter into the subject. Suffice it to say that the organs of nutritive or organic life include those of digestion, absorption, circulation of the blood, respiration and secretion; a series of phenomena of the most interesting kind, and which involve inquiries of the highest moment in the practice of medicine.

The organs arranged under the second of these classes are strictly of the animal kind; they enable us to move from place to place, to receive impressions of the varied objects that surround us, and to judge of the qualities and relations of these objects; hence we have for these purposes, first, the bones and muscles, or the passive and active organs of locomotion; secondly, the senses of touch, taste, smell, hearing, and vision, or a system of complicated apparatus of the most exquisite structure, by which we are in various ways brought into still more intimate relationship with external nature; and lastly, those still more remarkable central parts of the nervous system, on which the impressions made on the senses are concentrated and recognised, and through which all intellectual operation, sentiment, or instinctive propensity, emanate.

The organs of the third class, or those of reproduction, are essential to the continuance of the species. There is a term beyond which no organized being can survive; yet, though the individual being must perish, the species continues unimpaired. By the legitimate exercise of the reproductive organs a series of effects are superinduced, as remarkable and interesting as any in the whole circle of nature. These effects may be said to comprehend copulation, conception, uterogestation, and parturition—a series of processes by which a new being is formed, elaborated, nourished and protected, till fitted for an independent existence.

Many works since the time of Vesalius have been written on the special anatomy of man. In some, as in those of Winslow, Boyer and Cloquet, accuracy and minuteness are aimed at, without regard to the uses or functions of the parts. In others, as in the *Anatomie Descriptive*, of Bichat, the descriptions, though not less accurate and circumstantial than in the former, are uniformly found in more intimate relationship with physiology. There are likewise many works professedly devoted to physiology, in which much of the intimate structure of man is attended to. Of these I may mention the Elementa Physiologiæ of Haller, and still more particularly the Elements of Physiology, by Müller, of Berlin, translated from the German by Dr. Baly, and enriched by the lucubrations of the translator himself.

3.—*Of Comparative Anatomy.*—That department of anatomy which treats of the structure of the inferior animals is usually called comparative, although a comparison with the structure of man, or with any thing else, does not necessarily enter into the investigation. The subject is of great extent, and of immense importance in the prosecution both of special and general physiology. It includes a knowledge of the structure of the numerous orders, genera and species of radiated, articulated, molluscous and vertebrated animals, or an animated chain which stretches through a long and intricate succession of being, rising too in complexity from the monad or microscopic animated point, to the chimpanzé, the link which connects man to the inferior creation. Our discussions of this department of our subject, though of daily occurrence, will necessarily be very general, and subsidiary to human anatomy and physiology; but general though our demonstrations of comparative anatomy must necessarily be, I have no doubt that they will tend to increase the interest and usefulness of the course, and stimulate you also to a closer and deeper investigation of the subject for yourselves. To the Baron Cuvier we are chiefly indebted to the rapid progress this department of science has made during the last 40 years—a progress that seems almost miraculous, when we consider it as the result chiefly of one mind, but that mind was of no ordinary mould. I look upon Cuvier not only as the greatest naturalist and comparative anatomist, but also one of the greatest men that modern times has produced. I do not know which to admire most, his acuteness of observation and indefatigability in research, or his sagacity and intellectual profundity. Since the time of Aristotle, it will be admitted that his equal has not appeared. We have only to glance at his investigations into fossil animals to be convinced of his immense superiority. With a mind that could grasp the whole of nature's works, and with an acuteness that could penetrate to the very origin of things, he threw a blaze of light upon, subjects that seemed shrouded in eternal night matters which eluded the deepest search of all previous investigators, he dragged to the light of day; he gave a form, a local habitation, and a name to whole genera of animals now extinct, and which inhabited our planet when man and the present race of animals were yet in the womb of futurity.

In a subsequent lecture I shall advert at great length to the importance of comparative anatomy as a means of illustrating human anatomy and physiology; indeed all the great discoveries in physiology have been effected not so much by investigations into the human structure and functions, as by experiments instituted on the inferior animals. Look at the discoveries of Harvey on the functions of generation and circulation—of Bell and Magendie on the functions of the nerves—of John Hunter, Wilson Philip, Edwards, Müller, and others, on many of the vital organs and functions, and the high importance of comparative anatomy to the student of physiology will at once be apparent.

Many books have been written on this department of our subject, to a few only of which it will be necessary at present to allude.

I can recommend to your attentive perusal the Leçons d'Anatomie Comparée of Cuvier, the Outlines of Comparative Anatomy by Dr. Grant, and the Traité Elementaire d'Anatomie Comparée, by Carus—works in which the subject is treated systematically and fully, yet each in a different manner, and with a different object. You will find also many good articles on comparative anatomy as well as anatomy and physiology generally, in the cyclopœdia of anatomy, edited by Dr. Todd—

a work which reflects great credit on the industry and scientific attainments of the physiologists of this country.

4.—*Of Developmental Anatomy.*—Every organ in the body, as well as the body itself, has a period of commencement, from which it passes through various changes in its progress to maturity; these changes, and the laws by which they are effected, belong to that department of anatomy which we may denominate developmental. The period of man's existence may be included in two grand epochs, that of intra-uterine and that of extra-uterine life. The first extends from the moment of conception to the period of birth, and the second from birth to the last moment of existence, or to death. The anatomical and physiological history of man during the first of these epochs is fraught with intense interest. It is a history not only of the changes which the body, as a whole, undergoes, which are neither few nor unimportant, but also of those minute changes which take place in each organ from its invisible and inapproachable commencement to its perfect form, and in some instances to its full development. These changes consist not merely in an increase of size, a fact generally applicable to the organs of extra-uterine life, but in many curious and important transformations. Every organ is formed by the successive additions of new parts, and developmental anatomy treats of the order in which these additions are made, and of the physiological and pathological conclusions which may be deduced from this knowledge.

Besides the few excellent monographs which have been written on the development of particular organs, among the best of which are those of Tiedemann on the fœtal human brain, Serres on the spinal cord, Seiler on the eye, a succinct account will be found of the development of all the primary textures in the Anatomie Generale of Beclard, and in the Embryologie Humaine of Velpeau, and more particularly in the Principes d'Organogenie of Serres, an approach is made to a systematic and scientific arrangement of the whole subject of developmental anatomy.

5.—*Of Philosophical Anatomy.*—This designation, introduced by G. St. Hiliare, has been applied to that department of anatomy which treats of the fundamental type or model on which all the animal organs are formed—a subject extremely interesting and curious in itself and calculated to lead to many important physiological and pathological conclusions. G. St. Hilaire has attempted to show that amid the endless variety of living beings who inhabit this globe, and more particularly among the vertebrated division of these beings, a striking similarity, if not an identity of structure exists, and that the apparent diversity of form and structure of different animals is dependent on a difference of development merely of parts essentially the same. Although many of the opinions of St. Hiliare are more fanciful than just, still it must be conceded that his "Theory of Analogues," is exceedingly plausible, that his views of the elective affinity of organic elements and of the balancing of organs display an intimate acquaintance with animal organization and structure, and while we may call in question the accuracy of some of his "facts," and the soundness of some of his principles, there can be no difference of opinion regarding the originality of his views, and of the ultimate advantage to science of such investigations.

From what has been already stated, then, you will perceive that though in our practical course your attention will be confined to descriptive and relative anatomy, in the lecture delivered at this hour we shall take a much more extensive range and include in our investigations, general, special, comparative, developmental and philosophical anatomy. These subjects, it must be remarked, however, will not be discussed in the order now mentioned, but wrought up into a systematic whole. A few preliminary lectures will be given, illustrative of these subjects individually. But the whole will be taught, I conceive, to greater advantance in combination, and taught in subserviency to a full, useful, and scientific knowledge of human anatomy.

It will require no lengthened argumentation to prove the paramount importance of a knowledge of anatomy to the practitioner of the healing art; and as you are just about to enter this field of scientific research, with the ultimate object of fitting yourselves for professional practice either as physicians or surgeons, a few remarks on the relation which anatomy and physiology bears to medicine and surgery may not prove altogether useless. The object of medical science is to prevent, to cure, or to eradicate disease. Now disease in its mildest form is known to us generally by disordered function. Disordered function, however, cannot be recognised without a knowledge of healthy function. Healthy function cannot be understood without a knowledge of structure; and structure cannot be known without anatomical observation and scrutiny. There is, therefore, betwixt a knowledge of structure or anatomy, and a knowledge of disease, a close and intimate connection. If the structure is not known, the disease cannot be understood and consequently cannot be treated scientifically, or successfully. Physicians, are required to take enlarged and general views of the economy of man, both in a state of health and disease, and also to explain particular states and symptoms that exist in health, or are evolved by morbid action. But, can correct ideas of the workings of the whole economy be formed, if we are ignorant of the parts that constitute the whole? Or, can symptoms which depend on the situation or connection of parts be clearly comprehended if these parts are unknown to us?

If anatomy is so *obviously* necessary to the physician it must be of equal or still greater importance to the surgeon; it is to the surgeon what the illustrious Bacon has said of knowledge—it is power—power to alleviate pain, to eradicate disease, to save life. Surgical science may be viewed in a two-fold light; first, as embracing principles that are general or applicable to all the operations of surgery; and secondly, as referring to principles that appertain to particular operations. The *general* doctrines of surgery may be all comprehended in what is termed inflammation and its terminations; yet, all these are only certain processes or operations of the animal economy, and probably differing less from the healthy operations than might at first view be supposed. One thing is undeniable, that the man who is conversant with the healthy operations of the human machine will find little difficulty in forming correct ideas of the more uncommon workings of the system. But it is in the manual or operative part of surgery, that the importance of anatomy shines forth most conspicuously. The human body is a most complicated machine. In teaching anatomy, we indeed, try to unravel its intricacies by grouping the different parts into systems, as the osseous, the muscular, the vascular, the nervous, and the splanchnological; but this, though a useful, is at best a scholastic arrangement. The parts are never found thus arranged in nature, but bones muscles, blood-vessels, nerves, and viscera, are intermixed and blended, and to the young student apparently blended and intermixed in inextricable confusion. He can see no arrangement, and can scarcely conceive how any operation with the knife can be easily and safely performed. But the art of the anatomist expels the darkness and demonstrates an order and an arrangement of structures as beautiful as can be found in any other department of nature. The arrangement and relationship of these parts must be learned, however, before a surgeon dare venture to operate, and this knowledge can only be procured by studying anatomy. Compare the state of surgery in ancient and modern times, and you will see how much that science has latterly been benefitted by the cultivation of anatomy. The ancient surgeons were unacquainted with any effectual method of staunching the blood after operations, and the consequences, therefore, were often dreadful when they ventured to interfere. These interferences were often worse than death. If they cut, they afterwards seared with a red-hot iron. If they amputated an extremity, they either cut with a red-hot knife, or plunged the raw and bleeding surface in boiling oil or pitch to stem the torrent of the blood. The mind sickens at the bare recital of these barbarous and revolting expedients, and turns with delight to the introduction of the ligature by Ambrose Pare. This was the first grand improvement in modern surgery—an improvement springing essentially, however, from anatomy, and knowing as we now do, how much suffering humanity has been benefitted by a knowledge of the blood-vessels alone in reference to this single invention, we can easily conceive the mighty effects that would result to mankind by the successful cultivation of the whole circle of anatomy.

Anatomy is not only of deep interest, but a knowledge of it is absolutely necessary to your future respectability and success. If you are desirous of rendering your other medical studies easy, and at the same time pleasant, you must study carefully anatomy. It is the foundation upon which the whole superstructure of medical science must be erected, and if the foundation be unstable, how can the superstructure stand? Some of you are about to enter upon a new world of inquiry, and for the exercise of your various abilities you will find full play. Anatomy, as the science of organization, is yet in its infancy. The descriptive anatomy of the human body is more advanced, but this you know is but a small part of the science of organization, and in exploring the remaining part of this *terra incognita*, what successful results may not be anticipated, what brilliant discoveries may not yet be made. With an average share of ability, much may be accomplished, provided you proceed upon the right track and bring to the undertaking an honesty of purpose and an inextinguishable determination to succeed; and, gentlemen, if you are not forgetful of your own interests—if you are not deaf to the calls of suffering humanity—if you are not insensible and inaccessible to the generous and ennobling feelings and impulses of our nature you will not only fervently *resolve* to do justice to your studies, but carry that heaven born resolution immediately and perseveringly into *operation.*

LECTURES ON CHEMISTRY.

By JOHN SCOFFERN, M.D., Lecturer on Chemistry, at the Aldersgate School of Medicine.

The branch of electrical science termed *Galvanism*, or *Voltaic Electricity*, owes its origin to Galvani, Professor of Anatomy at Bologna, in the year 1790. It appears that this philosopher was phosecuting certain enquiries on the frog, relative to the nature of muscular irritability, during the course of which he found that the animal's limbs contracted on touching them in certain spots with the blade of a knife, or other metallic substance. Galvani, having remarked the universality of this result, began to speculate on its cause, and finally arrived at conclusions which the result of his experiments by no means warranted. The following were the tenets of his belief:—"That in the brain there exists a store of electricity, whence it is distributed to every part of the system, and resides particularly in the muscles. That the different parts of each muscular fibre are in opposite states of electrical excitement, like the two surfaces of a charged Leyden jar; and that contractions result whenever the electrical equilibrium is restored. That such restoration is effected during life, through the medium of the nerves, and may be effected after death by interposing a metallic conductor." Now, without troubling ourselves by an examination of the details of this theory, details, which, by the way, are altogether gratuitous—let us at once embrace the main fact, that, in the experiments just mentioned, the electricity noticed was regarded by Galvani to have originated in the animal; and that the metal, or metals, were merely considered as acting the part of conductors.

The theory of Galvani met with several opponents, of whom Volta, Professor of Natural Philosophy at Pavia, was amongst the most celebrated. He discovered that although one metal might, under certain conditions, produce the effect described, still it was much more effectually accomplished by two. He finally attributed the electricity generated, not to the animal, but to the contact of the two metals; of one metal with some adventitious body. Following up the train of enquiries to which those opinions gave rise, he constructed his celebrated pile—called the Voltaic

pile—formed by arranging plates of two dissimilar metals alternately, (the order of their recurrence being always maintained in pairs with a piece of moistened cloth, or card, between each pair.) It is strange how blind people are apt to be, to everything which opposes their own theory. Volta attributed all the electricity developed by his pile to the contact of different metals, — *then, where was the necessity of interposing pieces of moistened cloth?*

Subsequent investigators discovered that chemical action was always a concomitant of the development of electricity by Volta's apparatus. Fabroni even contended that the contractions produced by the pile on animals, depended on the heat developed by chemical action, or on the contact of metallic oxides with the animal tissue. This theory, fallacious though it be, had the effect of calling the attention of philosophers to the chemical changes which took place within the pile. Dr. Wollaston devoted particular attention to this subject. In the Philosophical Transactions of 1807, he published many ingenious experiments to prove that the electricity resulted from a previous chemical action, and was commensurate with it.

The third theory of the Voltaic pile is intermediate between Volta's and Wollaston's. It was proposed by Sir H. Davy, who inferred that the electrical current depended as well on metallic contact as on chemical action; the former, he imagined, first produced a disarrangement of electrical equilibrium, which was immediately restored by the latter—such disarrangement and restoration constituting a permanent current.

Supposing the elements of the pile to have been copper, zinc, and water, the explanation of the resulting electrical current, according to Davy's views, would be as follows:—"Copper and zinc being brought into contact, electrical excitement as the result. Zinc becomes + and copper.— The water in contact with the plates is composed of two elements, oxygen and hydrogen. Of these, hydrogen proceeds to the copper or negative plate, and therefore itself must be negative. Oxygen, on the other hand, goes to the zinc or positive plate, and must therefore be positive." It is evident that this theory assumes the necessity of metallic contact, as the *fons et origo* of all subsequent electrical action,—an assumption which is fallacious, as modern experimenters have proved.

The advocates for Volta's theory endeavoured to support it by reference to the dry pile of De Luc, an instrument which may be thus simply explained:—A glass tube is filled with discs of paper, gilt on either side with a different metal (silver and Dutch leaf are those generally employed), and the tube is furnished at either end with a brass knob. Such an instrument is capable of manifesting several electrical effects, and it has been argued that the electricity must be owing to metallic contact, inasmuch as the paper being dry, no chemical action could result; a fact also proved (as was thought) by the duration of the period which such a pile will retain its power. These arguments seem altogether fallacious. In the first place, the paper, although called *dry*, must necessarily contain some hygrometric moisture,—secondly, the metallic plates certainly do become oxydized. It may be argued that the oxydation is not commensurate with the length of time which such a pile will evolve electricity, but I cannot fall in with this idea. Although a De Luc's pile will remain in action for years, yet it is not always active; but, previously to using it, a terminal screw is employed to compress all the metallic plates together. Even then, the action of a De Luc's pile cannot be depended upon, and its effects at the best are but very trivial. Some years ago, when I assisted a lecturer on chemistry in this town, I called on a celebrated maker of philosophical instruments, the owner of a De Luc's column, no less celebrated. This I wished to borrow, having heard sundry eulogies as to its potency. Some how or another, I noticed that the fame of the column was not mentioned to the owner without some slight embarrassment on his part. The origin of his embarrassment I had no wish to pry into, and was in the act of turning away, with the instrument in my pocket, when the owner beckoned my return. For a second he said nothing, and I was in the act of turning away again; at last he enquired, with some emotion, "Do you assist Mr. —— in his lecture?" "Yes." "Then," said he, "before you hand him this column, *give the glass part a rub with your coat-sleeve.*" I did so. Electricity was generated by the friction—the gold leaves of the electroscope were deflected most magnificently—and the audience were very much edified by this instance of electricity *by contact*. I mention the fact, to prove how much the power of De Luc's apparatus has been over-rated, and how little reliance can be placed on class-room experiments illustrative of this instrument.

Such, then, are the chief theories of Voltaic action—we will leave them for a while, and proceed to enumerate certain forms of Voltaic arrangement. The pile, intimately connected as it is with the theory of Volta, is a very inconvenient instrument for most purposes, and is now seldom or never employed, except as a curiosity. Voltaic arrangements may be either simple or compound—the former are those which consist of the fewest possible elements necessary to produce Voltaic disturbance. For instance, an arrangement of *zinc, fluid, copper*, whether placed vertically in the form of pile, horizontally, or otherwise, is a simple voltaic circle. A reduplication of this series constitutes a compound Voltaic circle. All the various forms of Voltaic arrangements being so much more easily understood by inspection than by description, I pass them over, and confine my attention to the simple Voltaic circle, as most instructive. The usual plan of forming such an arrangement is by immersing two dissimilar metals, touching each other at one extremity, in a fluid which is only capable of acting on one of them, or, if on both, with different degrees of facility. One metal, and a fluid capable of acting upon it, will not develop a Voltaic current—but one metal, with a different fluid on either side, each effecting a different chemical action, is efficacious. The usual plan, however, is to employ two metals and one fluid. Knowing the relative facility with which different fluids exert a chemical action on different metals, it is easy to indicate the best theoretical voltaic arrangement. This will be best understood after an examination of the accompanying table:—

DILUTE NITRIC ACID.	STRONG NITRIC ACID.	MURIATIC ACID.	SOLUTION OF CAUSTIC POTASH.	YELLOW HYDROSULPHURET OF POTASSIUM.
Platinum,	Platinum,	Platinum,	Platinum,	Platinum,
Silver,	Nickel,	Antimony,	Silver,	Iron,
Copper,	Silver,	Silver,	Nickel,	Nickel,
Antimony,	Antimony,	Nickel,	Copper,	Bismuth,
Bismuth,	Copper,	Bismuth,	Iron,	Antimony,
Nickel,	Bismuth,	Copper,	Bismuth,	Lead,
Iron,	Iron,	Iron,	Lead,	Silver,
Tin,	Tin,	Lead,	Antimony,	Tin,
Lead,	Lead,	Tin,	Cadmium,	Cadmium,
Cadmium,	Zinc,	Cadmium	Tin,	Copper,
Zinc.	Cadmium.	Zinc.	Zinc.	Zinc.

Suppose the exciting fluid to be muriatic acid, then the best metals to form a Voltaic arrangement would be platinum and zinc: the next best, antimony and cadmium, *etc.* It is singular that the power of Voltaic electricity to give a shock, depends entirely on the number of alternations, independently of the extent of their surface;—but with respect to chemical effects, the reverse obtains. This fact has never been satisfactorily explained. Until within the last few years, the metals generally employed for forming Voltaic arrangements, were copper and zinc; but, lately, many forms of arrangement, infinitely more powerful, have been devised. Platinum, in the old forms of battery, would have been too expensive an element; but, in Groves' arrangement, this inconvenience is partly surmounted, and an instrument is formed more powerful than any Voltaic apparatus previously invented.

It is a great objection to most Voltaic arrangements, that their agency is so evanescent, thus preventing a continuous series of experiments. In ordinary arrangements of zinc, copper, and acid, the effect rapidly declines, partly from the decreasing strength of the acid employed, and partly on account of a deposition of metallic zinc on the copper-plate. Professor Daniell obviated this inconvenience by what he calls his constant battery, in which, by a very ingenious, but simple contrivance, copper, instead of zinc, is deposited on the copper-plates, thereby always preserving them bright and efficient.

We will now pass from the forms of Voltaic apparatus to the effects produced by the electricity evolved; and here I should remark, that, although identical with electricity developed by the machine, still its effects are very different. Voltaic electricity is developed in a quantity infinitely greater than can be accomplished by the machine—but of very low intensity; hence the peculiarity of its results. This distinction between intensity and quantity is felt almost intuitively by electricians, and still is very difficult to be explained. It is easy, however, to imagine effects not only dependent on the quantity of an agent, but also on the method of applying it. For instance, the ignition of a pound of gunpowder thrown loosely on the ground, would not produce so marked a result as an ounce fired in a cannon. Without pretending to demonstrate any precise analogies, I think you may associate the idea of electrical intensity with a small quantity of confined and ignited gunpowder; whereas, electrical quantity, apart from intensity, may be roughly assimilated to the other case.

I have already noticed that chemical action is necessary to Voltaic excitement; the latter, in its turn, becomes one of the most powerful agents in effecting chemical decompositions. Previously to my entering upon this subject, I must caution you against any confusion which might arise from an apparent contradiction in terms, in reference to the ends of a Voltaic arrangement. We will suppose zinc and copper to be the metals employed, and dilute sulphuric acid, the fluid. Now, a simple Voltaic arrangement of these elements would stand thus,—

+ Copper, acid, Zinc —

in which case the copper is positive, and the zinc negative. A compound Voltaic arrangement of the same elements stand thus,—

+ Zinc, copper, acid, Zinc-copper —

In which case the electrical energies seem reversed; but this is only apparent, not real; the explanation being, that in every compound Voltaic circuit, the two terminal plates are of no service, and might be removed without influencing the results. The reason of their being retained, is for the purpose of allowing several batteries to be joined together, when the plates, formerly terminal, cease in reality to be so. The effects of Voltaic electricity may be divided into physiological and chemical; the former do not materially differ from those produced by electricity from the machine; the shock, however, is not so violent as that from common electricity, but more persistent. Like common electricity, it has been employed in the treatment of many diseases, with various degrees of success. For such purposes, it is to be remembered that mere extent of surface in the metals employed, need not be regarded—number being the only requisite. The chemical effects of Voltaic electricity are most curious and important. No other agent has afforded us such means of elaborate decomposition, or has led to such magnificent and unexpected results. It was by the aid of Voltaic electricity that Davy achieved the first brilliant conquests in his extraordinary career, and accomplished the decomposition of the alkalies and the earths.—The investigation of these effects will form the subject of our next lecture.

Poisoning by Laudanum.—A young writer, M. Camille B., whose *debuts* at the *Comedie Francaise* had been remarked, has lately perished in consequence of a fatal imprudence. Being attacked with a slight indisposition, M. C. B. was directed by his father, who is a physician, to apply a cataplasm, into which a few drops of laudanum were to be poured, to the stomach. To alleviate his pain, which was very severe, he poured, instead of three or four drops, the whole contents of the bottle into the cataplasm, and went to sleep thus. The poisoning was almost instantaneous. The most prompt assistance which was rendered him was in vain; he died in a few minutes.

EXTRAORDINARY CASE OF ARTIFICIAL SOMNAMBULISM, AND CLAIRVOYANCE.

To the Editor of the 'MEDICAL TIMES.'

SIR,—Before I left London, you asked me to give you a written account of what I had just seen at Mr. Prideaux's, at Southampton. The reason I did not do so, was, that the patient I had seen was not mine; I was not the mesmeriser; and, as it was in his house we experimented, I could not assert, on my *own* knowledge, that there were not pipes going from his upper rooms down to his kitchens, &c., &c. True, I did not allow any of our *experiments* to depend on the honesty of either Mr. Prideaux, or his patient, for the *experiments* were not of a nature for collusion to be possible. Still, I thought I should appear with better grace before the public, if attesting cases of my own, and which took place in my own house, and until I should have such an opportunity I determined to remain silent on what I had seen; but, now that such an opportunity has occurred, I will relate it, and, in some future letter, will relate, also, what I saw and did at Mr. Prideaux's, at Southampton to whose kindness and forbearance, I am much indebted. I will now proceed to give you an account of what happened last night, here in my drawing-room, between the hours of eight and ten.

Caliste, now aged 22, was once a patient of M. Ricard, professor of mesmerism, here at Paris; after being cured by the latter, of his complaint, he was retained in the establishment of M. Ricard, some years, on account of his remarkable lucidity. At length, Caliste and M. Ricard, disagreed, I believe, on account of Caliste's immoderate love for the bottle, and they parted. M. Ricard will now not have any thing to do with him, and I believe, Caliste makes his living by being mesmerised for pay, by the Paris medical students, and who, by bad management and ignorance, I have no doubt, have much injured his mesmeric education, as much as intemperance has, doubtless, injured his lucid powers. I brought with me sealed letters from England to get read, unopened, should ever such an opportunity occur, and I applied to M. Ricard for his assistance, in the endeavour. He said he knew no patient then AT THAT MOMENT IN PARIS, so likely to read them as Caliste, provided he had lost none of the former power which he possessed, when mesmerised by him. I said I should be delighted to run the chance of a trial, and his clerk promised me to send Caliste to me, if by any means, he could get his address. A few days after, Caliste was sent to my house, and I saw him, for the first time in my life, the day before yesterday. We only exchanged a few words, in which, I told him what I should give him, and to come the following evening (last night), for me to mesmerise him, but to bring no one with him, as I was quite competent to take care of him. Last night, 5th October, Caliste arrived here at half-past 7, P. M.; I had invited to witness the experiments with three ladies, Colonel Kent Murray, Captain Cotgrave, R.N., and Mr. Jump. I commenced mesmerising Caliste, and in about seven or eight minutes, he passed into the mesmeric sleep, with a deep breathing and a shudder.

In a minute or two, we began our experiments. We wrapped up some cotton wool in some lint, and made two large pads, which we applied to his eyes, and over them, bound a very large, new, and white India silk handkerchief. Every one declared themselves satisfied he could not see. He then consented to play *ecarte* with one of us, and Capt. Cotgrave began. They sat at a card-table, and two packs of MY cards were produced. He took up one pack, and like lightening sorted them for *ecarte;* that is to say, he threw out all the cards below seven, without one mistake. They cut, and he dealt—he won every game, and, to the best of my observation, never lost the point, *except when the Captain refused to give him cards,* when, of course, it was a question of luck. He would frequently say, before he began to play (and all he did was with an astonishing rapidity) "You have lost;" and tell over the cards of his adversary as if he saw them, and never made a mistake. He knew the cards his adversary held, better than the Captain did himself. Colonel Murray then played with him, and with exactly similar results. On one occasion the Colonel cut for deal, and cut at the seventh card from the top, and before he turned it up, or knew himself, Caliste named the card. Now, he must either have seen through six cards, or round a corner, neither of which depended on any fault in the bandage, *even* if a misplacement *had* taken place, any more than his reading his adversary's cards. While playing, he seemed much annoyed by the brass hinge of the card-table, and for a long time we could not think the meaning of his fretful motions, till he complained of the brass, when we turned the table for him. We frequently inspected the bandage, and sometimes at his own request, though, indeed, the wonder of what he did was not at all dependent on it. I then begged him to tell me, out of ten sovereigns, the one I had mesmerised. He said he *disliked gold*, but begged for silver. I gave him ten crowns. One was marked by Colonel Murray, and given to me to mesmerise, and the Colonel ran his hands over the others—Caliste had his head *turned away,* and the bandage still well on—I placed the mesmerised piece amongst the rest, and turned my head away, fearing if I knew which it was, he would find out *through me*, and begged the Colonel not to touch *it*, but to push it about with the others, and alter the position of it. All the company had been shewn the Colonel's mark, and Captain Cotgrave also moved them about. Caliste took them all up, put one at top of the other, ran his nose, as if smelling, along the rouleau of crowns placed them upon the table, and said "The fourth piece is yours." He was right. He never looked at the faces where the mark was, and all was done with a *speed quite incredible.*

I then put him in contact with the Captain, and asked him about his health, and if he had lost any limb, or the use of any organ? He said he was then suffering no pain—that he had lost no limb. I asked if he was deaf or blind? The reply was, he sees better with one eye than the other; and on being desired to name which eye was the best, he named the left, which was quite correct; for the other eye was quite gone, though, unless looked into, not to be easily perceived. I forgot to mention that while Caliste was playing cards, I had all the lights put out, but one, which was put at some distance from Colonel Murray, so as only *just* to enable him to see his own cards. Caliste did not appear to be aware of the change for some time, but still played on and told his adversary's cards: but at last he said something about the candles, and we relit them. Another experiment we made, was to see if he could tell us the names of four cards, with their faces on the table. He said he could not, he thought, tell us the colour, but he would count the points for us, which he did correctly, only once he counted seven instead of ten.

I then gave him one of my sealed letters to read, but he said he could not, for he had never done such a thing, though he had seen into a wooden box (which box I have seen), but that if he tried three or four times, each time mesmerised by me, thought he could. It was curious to see him try: he applied it to his elbow, stomach, head, fingers, &c., and all with the greatest speed. I then proposed to the company trying on him an experiment, I had seen Mr. Brookes, in London, succeed with, but that I did not know if I should succeed or not, for I knew nothing of the patient's powers, or of mine over him, for I had never mesmerised him before. The experiment was to make him "hear" or "deaf" at pleasure. Without giving him any notice of my intention, I placed him in rapport with Colonel Murray, and begged the Colonel to keep up with him a running conversation. Captain Cotgrave was to stand behind him, and give me a signal when to make him deaf, and when to make him hear again. I stood behind him and on one side, with my legs, at about four and a half or five feet from him. At the signal given, I made him deaf, but using too much power for so simple a purpose, his head fell, his breathing was heavy, and he had just the appearance of a patient in a fit of apoplexy. At the given signal I made him hear, but again using too much power, he made a start as if frightened. We again tried the experiment, and as I used less power, the effect was much more *neat* and beautiful. I did not breathe on his ear to restore hearing, as did Mr. Brookes. Captain Cotgrave kept a sharp look out on me to see I was not any where near enough to touch a loose hair with my hand; which I kept at about a foot and a half from his head, and only allowed the hand to move *slowly* from the wrist, and, indeed, the hand or any motion was quite unnecessary.* We then gave him a French book, and opened it at two different places, which he read without difficulty, following the lines with his fingers. We took off the bandage and reapplied it, but still he read, and two words were of the *smallest* type, which I could not read at the same distance, though my sight is most acute. Colonel Murray then wrote on paper a sentence, part of which, Caliste read, but said it was too small, and indistinctly written for him; indeed, the words he read I could not make out at all. Colonel Murray then wrote what I send you enclosed in small writing, part of which, he read, but said it was too small; but, on Mr. Jump's re-writing it in large characters underneath, he read it all, but first said the word "bien" was "bon," and the word "Dommage" he said, was "De Manger," but, on our saying he was wrong, he at length read it correctly. He held the paper nearly at his arm's length; I then placed Mr. Jump en rapport with him, and begged him to tell his complaint. He touched the end of his fingers, and then carried his own to his nostrils and forehead. He said he had no particular illness or pain, but that he had a "nerveuse maladie par tout." This was strictly true, he had just suffered a heavy, loss and I had asked him to come to me to amuse him. Caliste could not bear the brass buttons on the jacket of the little page, with whom I placed him en rapport, but made him take off his coat before he would touch him. We also tried the community of taste, I eat a piece of sweet biscuit, which he said was "Gateau." I put a ginger lozenge in my mouth, which he said he did not know the flavour of, but supposed it was some sort of preserved fruit, but that he was not acquainted with those tastes. I then took some brandy from some brandy cherries with sugar in it, and he said it was some sort of liquor, brandy, or Rum or *something* of the sort. He then begged to be awakened, and I awoke him in half a minute.

Of course I shall continue my experiments on him for several sittings more, and will make him see behind him if possible.

If you will write me a line I will send you an account of our sittings, and afterwards of what I saw at Mr. Prideaux's, at Southampton, if such matters are likely to be agreeable to your readers.

Surely I cannot be charged with being credulous, for I have held out against each repeated fact in mesmerism, till I have had the same proofs as I have of my own existence—viz., my perceptive faculties, not *one*, but *all*, for one may be deceived as in the case of a conjuror pouring different wines out of one bottle, and even there one's sight does not deceive one for he really does it, but the bottle is divided, and there is a hole, plugged by his fingers, to each division of the bottle—still one of our senses may be deceived, but not all our faculties, as for instance the sun seems only as big as a cheese and our organ of size is deceived by the distance, but eventuality tells us that all objects appear smaller at a distance, &c., and we perceive our error. Were it asked why I believe in mesmerism, I should answer, because it has been subjected by me to the judgment of all my faculties, except the faculty of causality, and it has been declared by them true, and therefore stands exactly on the same footing in my estimation as the compass, the magnet, my existence, matter, space or light. I do not understand its cause, but must believe it and will not refuse myself, the uses and benefits it offers me because I cannot tell exactly its origin and its exact "why and wherefore."

Had I such evidence as I have had of all I assert to be true of mesmerism, I must believe anything, however extraordinary it may *appear to me*; I am not aware if such evidence would not make me believe a contradiction, such as three being but one,

yet at the same time quite separate. &c.&c., but there is no contradiction in mesmerism.

I remain, Sir, your obedient servant,

W. Macpherson Adams.

I must also in some future letter give you an account of Mademoiselle Virginié—what I have here stated, I am prepared to prove to any person or any number of persons. If any person whose name would have any weight whatever, as evidence of the facts I assert, will take a run over here, or if any such person be already here in Paris and will call on me, I will undertake to prove the faith of all I have asserted. If any gent., such as I have named, feels inclined to come here from England for the purpose, or if any such are coming here for any other pu. pose and would like to seize the opportunity, I shall only require that they bring a note from you just to prove their identity and their respectability.

TO THE THE ARTERIA INNOMINATA.

By G. D. Dermott, Esq., (Lecturer on Anatomy and Physiology to the Charlotte street School of Medicine.)

RELATIVE ANATOMY.

The Arteries arising from the Arch of the Aorta consist of *three trunks* which emerge from the cavity of the thorax, to supply the superior parts of the body; viz., the head, neck, breast, and the two superior extremities. They make their exit from the superior aperture of the thorax in the following manner:—

The *Arteria Innominata*, arises from the commencement or the superior and anterior part of the arch; passes obliquely upwards and towards the right side, in front of the trachea, and behind the upper part of the first bone of the sternum; and bifurcates behind the right sterno-clavicular articulation and about an inch and a half above its origin, into the right common carotid and right subclavian arteries; the first ascends on the longus colli muscle by the side of the trachea; the latter passes outwards across the upper surface of the right first rib, within the lower part of the neck, and next descends beneath the clavicle into the axilla. Sometimes the innominata bifurcates much higher, and crosses the trachea on the lower part of the neck above the sternum.

Descending in front of the arteria innominata, from left to right, and sinking into the thorax behind the upper part of the first bone of the sternum is the left vena innominata, which at this point generally receives some of the thyroid veins.

Anteriorly, inferiorly, and to the right, the right vena innominata bounds the artery—and more immediately inferiorly, and to the right, is the cul de sac of the right pleura.

Descending anteriorly to the arteria innominata, and between it and the vein, is the superficial cardiac nerve. The order of the parts (from before backwards) behind the upper part of the first bone of the sternum is, the interclavicular ligament—left vena innominata—arteria innominata—trachea—œsophagus.

To apply a Ligature upon the Arteria Innominata.—This artery has been tied in the living body, by Dr. Mott of New York, in 1818; by M. Graëfe, of Berlin, 1822. Both cases terminated fatally. Dr. Mott's on the 26th day, and M. Graëfe's on the sixty seventh. The head and superior extremity were, in both instances, duly supplied with blood by the collateral inosculations.

The following mode of performing the operation is the one usually recommended:—

Let the patient's head and neck be moderately extended backwards, which will rather have the tendency, by drawing upwards the trachea, to elevate the arteria innominata, inasmuch as the trachea is immediately behind it. Commence the first incision in the median line of the neck above the sternum, and carry it horizontally outwards (towards the right) above the clavicle, for nearly three inches, through the integuments. Carry another incision, of nearly an equal length, from the commencement of the preceeding one, upwards, in correspondence with the anterior edge of the sterno-cleido-mastoideus muscle; the two forming with each other a ⅃. Dissect the flap of integuments backwards, when the origin of the sterno-cleido-mastoideus will be exposed. Next pass a director from within outwards behind the sternal origin of the sterno-cleido-mastoideus, and cautiously but completely divide this part of the muscle. This will expose the lower parts of the deep cervical fascia, the sterno-hyoideus et thyroideus muscles, which must be most cautiously divided in the same manner. Next trace downwards with your finger, the carotid artery to its origin, which, if regular in its origin, leads you to the arteria innominata; pass the ligature behind the latter from within outwards The best aneurismal needle for this purpose, is that invented by L'Estrange, of Dublin. The position of the left vena innominata, which closely crosses the front of the artery nearly at right angles (and which will have to be depressed towards the thorax by the fingers of the operator) during the operation of tightening the ligature, must be particularly borne in mind.

When the innominata is tied, the blood is carried into the right carotid, and thence into the subclavian by the inosculations in the thyroid body—the circle of Willis also into the opposite subclavian by the junction of the two vertebrals; and from the aorta direct to the axillary and subclavian trunks by the intercostals inosculating with the external thoracic arteries.

The Arteria Carotica Sinistra arises from the middle and highest part of the arch of the aorta, immediately behind the arteria innominata, so that there is no evident space between the carotid and the latter; it is also at its origin rather before the left side of the trachea; it ascends, making a very slight inclination backwards and to the left, so that, after commencing in *front* of the left side of the trachea, gets by it, and against the longus colli muscle. It then ascends like the right common carotid.

The Arteria Subclavia Sinistra, arises from the upper and posterior* part of the arch of the aorta, at a little distance behind the left carotid, and consequently nearer to the termination of the arch of the aorta and the dorsal vertebræ. Although, as already stated, there is no positive interstice between the origins of the left carotid and the arteria innominata, there *is* a decided space between the origin of the left carotid, and this, the left subclavian, notwithstanding the two latter pass to the *same side* of the body.

The left subclavian passes upwards from its origin bearing somewhat more to the left than the left carotid, so as to emerge from the thorax posteriorly, but distantly, to the articulation of the first bone of the sternum with the cartilage of the first rib; then, getting on a level with the left first rib, it arches across it and between the two scaleni muscles; whilst still upon the upper surface of the first rib, like the right subclavian, it emerges from between the two scaleni, and dives downwards beneath the clavicle and subclavian muscle into the axilla, to becomo the axillary artery.

I think that by means of an inverted T incision, and dissecting the two flaps laterally, that the arteria innominata could be easily secured without the division of any muscle. In injecting subjects, a single longitudinal incision between the lower parts of the sterno-cleido-mastoidei, and carried downwards over the first bone of the sternum, is quite sufficient for the introduction of the pipe into the arteria innominata, and even into the commencement of the left common carotid, and that most readily; I also, when injecting from this point,make use of the same incision for introducing a pipe into the commencement of the left subclavian.

(To be continued.)

ROYAL COLLEGE OF SURGEONS, LONDON.

List of gentlemen admitted members on Friday, October, 7th, 1842:—

R. E, Adams, W. Thomas, J. Coman, H. G. Walker, H. St. John Clarke, G. Stockil. J. Christie, G. H. Maadsdoop, A. G. Purchas, J. Kenyon, H. Greaves, H, C. Thurgar.

* The terms superior, inferior, anterior, and posterior, are used in these descriptions in relation to the erect position of the body.

EXTRACTS FROM FOREIGN JOURNALS.

(For the 'Medical Times.')

French.—*Resection, with Disarticulation of the Lower Third of the Radius.* By Dr. P. Ricord, of the Hôpital des Vénériens.—*Case:* Joseph Vivian, 23 years of age, a labourer, was received into the *Hopital du Midi*, on the 13th of January, 1841. This patient, born of healthy parents, and himself possessed of strong constitution, had been affected at the age of 12 years, with an abscess near the internal condyle of one of the femurs. This abscess had left no trace behind it, and the patient had since enjoyed good health. Eleven months before his entrance into the hospital, after his usual labours and without any known cause, he was taken with severe pains and swelling at the outer and lower part of the right fore-arm. Two months afterwards, abscesses formed upon this region, and were opened in another hospital. It could easily be perceived on probing the wound, as well as from the nature of the suppuration, that one of the bones of the fore-arm was diseased. Fresh abscesses occurred, and the patient entered the hospital where he was treated, for four months, by emollient and tonic medicines. The following was his state when he came under my care: the lower part of the diseased limb was double its natural size, the swelling extending over the wrist-joint to the hand. The posterior surface of the limb was pierced with five fistulous gaping openings, of a fungoid appearance, and which gave issue to a sanious pus. Upon the anterior surface, four similar openings were perceived, through which the probe might be passed to the orifices on the back of the arm. The fleshy substance was hard and solid, in several points, resembling *lardaceous* tissue. In the various movements of the fore-arm and of the hand, we could scarcely distinguish the projection of the muscles or tendons. Although the patient did not experience acute pain, he felt a constant state of suffering, which, added to the abundance of the suppuration, had induced a state of fever with exacerbation towards night. He was much emaciated, and from time to time affected with diarrhea. Having discovered, by means of a probe, that the greater part of the inferior third of the radius was in a carious state, and taking into account the bad condition of the soft parts, I at first thought, like those surgeons who had seen the patient before me, that amputation of the fore-arm was the only resource left. But, after a most careful examination, and after being perfectly satisfied that the ulna was quite free from disease, that the radio-carpal articulation was still sound, although the disease of the radius was bordering close upon it, I decided on an attempt at the preservation of the hand, by removing only the diseased parts. On the 9th of March, 1841, I proceeded to the *resection* of the lower third of the radius and to its *disarticulation*. For this purpose, and with a view of preserving, as much as possible, the muscles and tendons, I followed the principles laid down by M. Jules Guerin, in reference to sub-cutaneous operations, and made a simple longitudinal incision along the outer edge of the radius, commencing below its middle part, and terminating just beneath its styloid process. The skin, as much as the state of the parts permitted, had been previously drawn backwards, so as to prevent the parallelism after the operation, between the outer wound and that of the deeper seated soft parts. This done, the radius was isolated, along its inferior third, by means of a curved bistoury, taking care to keep the knife close to the bone, so as to avoid, as much as possible, the muscles and their tendons. After having completely denuded the

bone, it was in the first place divided at the union of its lower and middle thirds, by means of a *chain-saw*. Directly afterwards, keeping the edges of the wound separated with the blunt hooks, the external and antero-posterior ligaments of the radio-carpal articulation were easily divided with the bistoury, and the radio-ulnar joint cut through with two strokes of Liston's scissors.

The operation was less tedious than I had expected; the patient bore it with great courage, and whether from the care with which the dissection was performed, or from the state of the tissues, not a single artery required tying. After the operation, the wound was brought together so as to unite by the first intention. The limb was placed upon a pillow, with the hand raised, and the parts covered with compresses moistened with cold water. A circumstance worthy of remark is, that immadiately that the *pronator quadratus* was divided, contrary to what takes place in fracture of the lower part of the radius, the hand was forcibly turned towards the ulnar side.

The removed portion of bone was greatly altered in structure throughout its whole substance, commencing half an inch below its upper extremity: being thickened, softened, and infiltrated with pus; presenting also in various parts, points of necrosis which were more or less detached from the carious bone. Without giving the daily details of the results of the operation, I shall merely say that by the the continued employment of the cold water dressing, all febrile re-action was prevented, and but two small abscesses formed which required opening: the one on the back of the hand, the other on the fore-arm. Six months, however, elapsed before the soft parts returned to their natural state and the fistulous passages became completely cicatrized. During this time, some small spicula of bone escaped by suppuration, as well as portions of tendon. It was only towards the fourth month that the hand, which formed an angle of 45 deg. with the ulna, became gradually straightened, in proportion as the point whence the radius had been removed was filled up by *inodular* tissue. At the same time that this straightening of the hand took place, it became slightly turned towards the anterior surface of the fore-arm, so as to allow a somewhat marked projection of the ulna backwards.

With a view of assuring myself of the perfect cure of the patient, as well as to give him time to gain as much strength as possible in the hand thus saved, I have kept him in the hospital up to the present time. The cure of this man is now complete; and, although his hand is partly deprived of the movements of pronation and supination, as well as of those of flexion and extension, he can write with ease, employ his hand for all the purposes of life, and carry things of considerable weight, such as a pail of water.

Instances, somewhat similar to the above, have been previously recorded; yet this case presents peculiar interest, and should encourage us to have recourse to an operation, perhaps, too much neglected, but which can hardly be too strongly recommended; for it may, in some particular cases, be substituted for amputation of the fore-arm, and thus preserve a useful hand to the patient.

TO CORRESPONDENTS.

A. M.—*Beck's work, a new edition of which has just appeared.*

The continuation of lectures by Orfila, Nottingham, *and* Serres, *next week.*

We have several Correspondents to thank for Country Journals.

Mr. H. W.—*We have received many testimonies of approval and kindness from our Country readers; but the most solid, is certainly that of our Correspondent,* H. W., *who sends us a basket of prime game. We have a very high opinion indeed of* H. W.'s *taste.*

The case from Bloxworth may as well be suppressed. The whole was a tissue of blunders.

Mr. Rankin.—*We have inquired, but are not able to give the information asked.*

A. H.—*The circumstance referred to, will make no difference in the* "sensations."

Mr. Coles, the ingenious machinist, has sent us the greatest of his inventions, a genuine poem of his own composition—the first-born of his old age,—and (we believe) of his young muse. Milton and Mr. Coles seem to have one thing in common—their Castalian founts both overflow about the autumnal equinox, and partly as a pyschological curiosity—and partly because it will (we are told), *produce an astounding sensation among the profession, we honour the extraordinary bantling with a place in our pages:—*

When first contagion spread its baneful breath,
Throughout the earth and sow'd the seeds of death:
A direful agent soon it singled out,
'Twas rheumatism, parent of the gout!

This painful racking foe to mortal's health,
Bore off its victims, as it were, by stealth;
Nor could the wisest sages of the day,
Arrest its progress, or the pain allay.

The period soon arriv'd when studious care,
Reclaim'd the thousands from their sad despair;
Rheumatic torture fled throughout the land,
From the Peruvian Rheumatic band!

"Coles," Patentee of many useful schemes,
Not based on feeble theoretic dreams;
Discover'd that a noxious atmosphere,
Engender'd Rheumatism every where.

Dampness of clime, foul vapour, or keen frost,
He wisely judg'd, nurs'd Rheumatism most;
Nay, from experimentalists he found,
That of all soils 'twas worst on British ground!

To quell this torment was his study bent,
Relief to mortals, was the sure event;
Mankind received such benefit, "that fame
Made Rheumatic Bands the general theme,"

Some of the Faculty came "learned too."
Writhing with pain, as many others do;
Could he, "their importunities withstand?"
Not he, indeed, "they all would have the Band."
Amazing where their virtues, "they proclaim,"
Blood circulating through ev'ry vein;
Their muscles *strenghtened and their* limbs *work'd free,*
Exclaim'd, foul enemy. *"we're conquer'd thee!"*

Sed Satis.

THE MEDICAL TIMES.

SATURDAY, OCTOBER 15, 1842.

Fy on't! O fy! 'tis an unweeded garden
That grows to seed: things rank and gross in nature
Possess it merely. HAMLET.

THE sufferings and death of the poor lady whose case we published last week, furnish matter for solemn and useful consideration. The lamentable victim of individual ignorance and negligence, she was still more the victim of a frightful system; and her death suggests to us a harrowing reflection on the multiplied murders which must necessarily come out of the same source, but which are for ever hidden from the world by the absence of circumstances so fortuitously striking and singular. Mindful of our consceration as journalists to the public's weal, we take our stand by her murdered corpse, the eloquent representative of many a less known victim, and summoning to our side, as unimpeachable evidence, the unpunished surgeon and druggist, we boldly arraign our governors for their breach of duty to the people. We bring the case of this injured woman before the judgment-seat of the public, and tell the government "this is your work!" We bring forward the enormous list of suicides, and we say, "your hand has been here!" We go to the sessions and assizes, and, marshalling the poisoning culprits, we exclaim, "behold your instruments!" We present the registries of druggists' victims mutilated, poisoned, killed in ignorance, negligence, or cupidity, and we cry, "their blood is upon your head! Justification there is none, and excuse avails not. The system is your work, and the power of remedy lies in your hand and is unused. You have left poisons free of access—as water: you might have made them unattainable save by doctors' prescriptions. You have left the druggist uneducated; you might have secured his perfect competency. You have vested profitable malpractice with impunity; you might have guaranteed its certain punishment. You might have made the druggist's business, prospects, property, liberty, life, the graduated forfeitures of negligence or wrong; and, while leaving the public at the mercy of his ignorance or sordidness, you have placed all these beyond the reach of justice. To the large extent, therefore, which these and *such* precautions would abate injury, or save life to that extent, we charge on you "that you are not guiltless of wrong!"

On what plea, we should be glad to hear, shall our government escape this grave responsibility? Whatever reasons there are for the existence of a government, are reasons for that government's taking a primary care on this vital matter. Government exists to protect individuals from one another's lawless excesses and criminal passions; to save, consistently with social good, the largest possible amount of their unintringed possession and enjoyment of their property—but, above all, of themselves — their health — their lives. To neglect its people's lives, therefore,—to leave them to negligence, when care can be easily secured—to commit them to ignorance, when knowledge may be guaranteed—to throw them at the mercy of every caprice, and every temptation, and every accident, and every vice, when these conditions may be easily provided against;—to do all this, we say, is for a government to forsake the very first of its duties. No complaint can be made of the government's lack of zeal in protecting its people's material *property*. In every loss of this kind the law is liberal enough in providing punishment on one side, and satisfaction on the other. If a shilling's value be lost to us through fraud or theft, we have the whole machinery of law ready at our hand for the quick restitution of the loss, or the severe punishment of the offender. Are health and life—the most valued of our possessions—of less consequence, or more easily protected? Or, are they in less danger from negligence, ignorance, avarice? We say, then, that our present loose, irregular, and heterogeneous system, which

makes human health and life dependent on chance-discretion, chance-knowledge, chance-industry, chance-virtue, nay, even chance-good-humour, is replete with calamities for the public, and that it is the immediate duty of government carefully to provide its people with the very best system that enlightenment can suggest and wisdom enforce, in reference to *all* the relations the public have or may have with any portion of the medical community.

If there were wanting any collateral proof of the striking absurdity of leaving the body of druggists in their present anomalous and manslaughtering position, we find it abundantly offered in the singular fact of their uniting themselves into an association, for the avowed purpose of doing the government's duty—doing that which every other government in Europe has done for the same class of tradesmen. Since the day that Don Quixote set upon his enterprize of protecting the distressed virtue of Spain, there never was a scheme half so enormously extravagant as that of the concoctors of the Pharmaceutical Society. Except the absurdity it pretends to cure, nothing in the present age of common place wonders distantly resembles its absurdity. It is not only a libel on the government, and on the character of our country for enlightenment, but on that common sense, for which British tradesmen have been so pre-eminently distinguished. They—the drug vendors of London—are to raise the English *Pharmaceutists*, (the very *word* applied to our druggists conveys a volume of satire) to the level of the educated *pharmacien* of France and the continent, to put them in keeping with the advance of the science, in harmony with the wants of the age,—in one word alone, and unassisted by law, to reconcile their *confreres'* ignorance, their negligence, their ambitious avarice, with the claims of justice, the requisitions of science, and the safety and comfort of society. Did a fevered patient ever *dream* of anything so preposterous?

Without education themselves they are to secure the education of their brethren—unexamined themselves they are to examine them. Without a diploma themselves, save a self given one, they are to impose diplomas on other's. Without authority to *advise*, they are to command—without power to enforce, they are to punish; in one word, they are to give what they have not got, to do what they can't!

In the name of common sense, in what way, or by what agency do these gentlemen expect to do any good? What is wanted are the very things which the men they represent are most interested in opposing. *First*, how insure competency? If the men are competent no examination do they need. If they are not, no examination need they stand. And how enforce it? By giving them the privilege of paying a guinea a year, *pro bono publico*, with the chance for a larger sum, and a greater expenditure of study, of getting a diploma, which is not worth the price of its printing, an ornamented etching, 24 inches by 19½, signed by some brace of London shopkeepers, possessed gratuitously by hundreds of tinkers and tailors, who thought proper to sell drugs, and apply for it some twelve months precedently! Why, if they even insisted on an examination distantly respectable—insisted even on a reduced scale of competency, the society would be extinct before the next annual subscription. If we wanted evidence of this we have it in the September number of the Society's organ, which favours us with these significant admissions. "In the law respecting examination, an exception was introduced, empowering the Council to admit, *without examination*, on payment of an entrance fee, *such persons* as had *been actually* in business on their own account prior to July 1st, and who might fairly claim this indulgence!" Again, "the Council have determined to moderate the severity of both the minor and major examinations *in the first instance*." And, secondly, how secure their brethren's respectability, when they dare not express, even an opinion on the common, universal *crime* of druggists' *prescribing* and even *visiting?* Why, of the three or four thousand members or associates they have on their books, we would defy them to name one hundred who do not desert the legitimate calling of pharmacy—and peril human life, for the paltry prospect of selling an extra box of pills, or a mixture.

We say, then, to these gentlemen, that tumid as now looks your society, it is only expanding to burst the more surely. Like a lofty house of cards, you cannot touch or breathe on it without renewed danger of its fall. Like the mist of a summer morning, created, illuminated, beautified by the rays of the very body that will yet disperse it; a short time has only to pass, and the scene will reveal to our gaze but the place where it *has* been! Already you feel that you have raised a power, which, incapable of controlling itself, is beyond the control of its creators—which moulds, who thought of moulding—governs, who thought of governing—and makes the law of your movements not what is right, but what is safe; not what is just, but what will please: and we need no gift of prophecy to assure you that every hope your society has nursed, it will falsify—every expectation it has raised, it will frustrate—the divisions it would soothe it will exasperate—the bad practices it would annihilate, it will fortify; and, living a thing of promises, and dying an object of pity or of laughter, will deserve to have its epitaph written something in this fashion!—

"*A well meant project—rife of good* FEELINGS, *and naked of good* THOUGHTS, which, originating in the luxuriance of benevolence, was sustained for a while by *the excesses of imagination, and perished prematurely of that malady fatal to so many other members of the Family of* SPECULATIONS—*the want of heroic perfections in the public—and of* common-sense *imperfections in the founders!*"

CASES OF PERITONEAL SECTION FOR THE EXTIRPATION OF DISEASED OVARIA. BY THE LARGE INCISION FROM STERNUM TO PUBES, SUCCESSFULLY TREATED.

By CHARLES CLAY, Member of the Royal College of Physicians, London, of the College of Surgeons, Edinburgh, and Lecturer on Medical Jurisprudence, &c. Piccadilly, Manchester.

THE following remarkable and important case is, I believe, the first instance of this operation (by the large incision), having been performed in England as practised by Dr. Macdowal, of Kentucky, in America, and Mr. Lizars, of Edinburgh, for the particulars of which I refer the reader to the valuable and able work of Mr. Lizars, on the extraction of diseased ovaria, who has entered so largely and elaborately into the history as well as the arguments for and against this bold operation, strengthened by his own experience, as to render my labour in the following details comparatively easy. The success of the operation I am now recording is even more gratifying to me than the fact of its being the first (as I stated before) in England. On this point, however, I do not wish to be misunderstood; I am aware of the cases recorded in England, where an operation was performed, having for its object the removal of the ovarian cyst, by Messrs Jeffreson, King, West, and Philips, the majority of whom were unfortunate in their results; it is, however, necessary to state, that the plan of operation pursued in those cases, was the one recommended by Mr. Jeffreson; viz., *A small incision of one and a half or two inches in length in the abdominal parietes, through which incision the ovarian sac was then punctured with a trocar, and when emptied of its contents, the sac itself drawn through the incision, its pedicle tied and separated.* On the contrary, the operation performed by Dr. Macdowal, of Kentucky, in America, Mr. Lizars of Edinburgh, and myself, is widely different. A large incision of eighteen or twenty inches in length, or from the ensiform cartilage to the pubes, the ovarian tumour fully exposed, its pedicle and adhesions separated, its vessels secured, and the whole mass removed entire. A slight glance will be sufficient to distinguish the difference between these operations. After having given the particulars of the case on which I have operated, I shall make some general observations, as to the comparative merits of the plans alluded to; and endeavour to justify some little deviation, not only in the plan of operating, but also as to the subsequent treatment from what has been pursued by others. I shall then, in the first instance, direct the attention of the reader to the early history of the case.

EARLY HISTORY OF THE CASE OF MARY WHEELER.

Mrs. Wheeler, of 75 Heyrod Street, Ancoats, Manchester, applied to me on the 10th of June, 1842, for my opinion, in consequence of an abdominal enlargement, which had existed three years or upwards, and about which she felt very uneasy. The following particulars were related by her; she was then in her 46th year, had always enjoyed a tolerable share of good health; she had had eight living children, and one miscarriage, and was twenty-three years old when the first child was born. At the latter end of 1839, she began sensibly to enlarge at the lower part of the abdomen, as though she was in a state of pregnancy. The swelling might have been of longer duration, but it did not particularly arrest her attention till the period above stated; at this time, her neighbours rallied her on being in the pregnant state, but she did not think herself so, as menstruation appeared at regular intervals. From February, 1840, the enlargement in-

creased more rapidly, still the catamenia regularly appeared. From the first commencement of the enlargement, to the latest period of its existence, she never felt any particular pain from first to last; the sensation was more that of weight, and incumbrance, than any thing else; nor can she recollect on which side the enlargement first began; but thinks she felt more inconvenience, and earlier, on the right, than on the left side. In the autumn of 1841, she consulted different medical men, none of whom, gave her any hopes of relief, and one told her it might burst of itself. She was of a constipated habit, never remembers having received any injury, had no occupation but that of attending her family, and recovered well and rapidly from all her confinements.

At the time of her consulting me (June 10th 1842) she was much emaciated, tall in person, of a sallow countenance, and appeared as large as a female in the ninth month of gestation; menstruation still regular, complained of great weight and incumberance, but had not suffered any particular pain. I proposed calling on her at her own house, with the view of making a proper investigation; to which she readily consented. On examination, per vaginam, I found the coats of the vaginal canal protruding outwards to a considerable extent, which circumstance must have existed for some time, as the parts protruding had lost their natural texture and character, and were hard and dry, as a piece of fish skin; the pelvic cavity was filled by a large tumour, so completely, that its extent could neither be defined, nor could it be moved by the finger in the slightest degree; the tumour appeared distinct from the uterus, and the uterus itself was lifted up higher out of the pelvis than usual, and the os uteri rested against the upper and inner portion of the symphisis pubis, and was very much flattened; the external abdominal parietes presented to view a distention quite equal to the ninth month of utero gestation,—it was of very unequal character, exhibiting protuberances in various parts, not unlike what the head, limbs, &c., of a child would present if escaped from the uterine cavity, and lying immediately under the parietes of the abdomen, rendered thin by great distention. The case was evidently an enormous tumour, occupying the whole abdominal and pelvic cavities, and from its unequal appearance, was, in all probability, composed of various sacs. The vagueness of its history, and its central position, did not clearly point out where its attachment might be, though it was most probably to the uterus or its appendages—the ovaria; the tumour was easily movable under the parietes, and a small quantity of ascitic fluid had been deposited in the abdominal cavity, which gave the tumour the feeling of floating in fluid, and led to the opinion that it had no adhesions beyond its pedicle, by which it was attached. The left iliac region was more densely filled than the right; but the history of the case rather encouraged the idea that the origin of the disease was on the right side. I requested my friend, Dr. Radford, (an experienced practitioner and physician to the Manchester and Salford Lying-Inn Hospital,) to give me his opinion on the case; who, after a most careful examination, pronounced it decidedly an ovarian tumour of considerable size, with a small quantity of ascitic fluid, and, from its mobility under the parietes, he considered there could not be any adhesions beyond its principal attachment; that it most probably arose from the broad ligament on the right side. I afterwards obtained the opinion of several other medical friends on whose judgment I had great reliance, all of whom confirmed the opinions previously given. It was also considered by Dr. Radford and myself that no effectual means of relief presented itself but that of extirpation. In the meantime a trial of the iodine was adopted for some weeks, but without any sensible diminution of bulk, and as the size of the tumour was too great to expect relief by absorption, and the system appeared to suffer from the effects, of the iodine, I at once discontinued it, particularly as my patient began to express herself earnestly desirous of an operation—respecting which I neither persuaded her to, nor dissuaded her from, but faithfully detailed to her the importance and magnitude of the means she sought—pointed out the particulars of every case on record, with the results, and rather, if anything, depreciated than added to the chances of recovery. Still she was determined I should operate, and the calm, deliberate manner in which she weighed the matter, convinced me I had a woman of no ordinary nerve to deal with—and that, in itself, was a point of considerable promise towards ultimate success. Under this view I promised to perform the operation, provided I could obtain the sanction and co-operation of my medical friends, for which purpose I again solicited their attention to the case, *with the view of extirpation;* amongst whom Mr. Wilson, a surgeon of great experience here, approved of the plan proposed, and with the promise of their cordial co-operation, I fixed on the afternoon of the 12th of September, 1842, for that purpose. I now felt fully sensible of the deep responsibility I had undertaken, in engaging to perform an operation that had no precedent in this country, and but few elsewhere; an operation that yielded to none in its importance, and, as to magnitude, greater than any other in the field of operative surgery. The difficulty of obtaining the countenance of my medical brethren, in a path untrodden before in this kingdom, came over me in full force; but the woman's earnest appeal for relief, and a consciousness that no other mode of effectual relief presented itself, that I had not sought it for the mere whim, determined me to meet the matter fairly and abide by the result; although I was perfectly aware that if the case proved unfortunate the world would not be wanting in arguments to condemn me for rashness, if not for an unjustifiable attempt to render myself notorious. But professional men well know that the notoriety attending unfortunate results of operative surgery is far from being enviable, and more than counterbalances the good from the successful attempts: hence the truth of the old adage—"a good report goes far, but a bad one much farther." That the public may frequently commit an error of judgment in such cases I can readily conceive, from the incapability of ascertaining the true nature of all the *pros* and *cons* connected with the subject, but it is to be regretted when professional men condescend to be partial in their judgment. As an instance I might quote Dr. Ingleby, of Birmingham, who, in his public capacity as a teacher, says, "*of Mr. Lizars' cases I forbear to speak;*" after which he proceeds to advocate the plan, as proposed by Mr. Jeffreson. Now, what is the fact? In many cases, as I shall afterwards prove, the mode pursued by Mr. Jeffreson is not only impracticable, but really absurd; and at the very time Dr. Ingleby makes his assertion, more cases had been successful according to the number operated upon by Mr. Lizars' plan than that of Mr. Jeffreson. I find connected with the Jeffreson mode eight cases, of which five were fatal. With that of Mr. Lizars', four by himself, three by Dr. Macdowal, of Kentucky, one by Dr. Smith, of Connecticut, one by L'Aumonier, in France, and one by myself, making eight, of which only one was fatal, and that with great propriety might have been attributed to other causes. Under these circumstances, I need scarcely add that I determined in favour of the large incision, as proposed by Mr. Lizars' and Dr. Macdowal, of America.

PREPARATORY TO THE OPERATION.

Having, therefore, fixed on the 12th Sept. 1842, I called on my patient on the evening of the 11th, found her in excellent spirits, pulse 70, calm and soft. I gave her ten grains of inspissated ox-gall, ordering a repetition of the dose early in the morning, if the bowels had not been previously moved. In the forenoon of the following day (the 12th) I found the bowels had been effectually cleared of fœcal matter, accompanied with considerable flatus. The thermometer indicated the temperature to be 68 deg. and the room not being a large one, coupled with the expectation of six or seven medical friends at the operation, I judged it unnecessary to raise the temperature artificially. At three o'clock p.m. the following gentlemen assembled at my own house:—Dr. Radford, Dr. Black, Messrs. W. C. Vaudrey, Nursaw, G. Southam, J. J. Southam, surgeons, and Mr. Higginbottom, nephew to Dr. Radford.

Before proceeding to my patient, I stated very briefly to the above gentlemen, the plans I wished to put into practice; embracing the following particulars. 1st. That I considered the temperature of the apartment would be sufficient when all were assembled in it, without raising it artificially. 2nd. That in the first incision I should leave the umbilicus to the left, but approach the central line as nearly as possible, from sternum to pubes, believing I should find the pedicle attached to the right broad ligament of the uterus, as slightly indicated by the history of the case. 3rd. To prevent eversion of any part of the wound when brought together by suture, I had taken the precaution of marking the abdomen with fine thread, dipped in a solution of nitrate of silver, crosswise to the incision, that the same parts might be brought in exact apposition when the tumour was removed, and the parts flaccid. 4th. That I should use more of the interrupted sutures, than had been done in the cases by Mr. Lizars. 5th. That I did not wish the intestines to be handled even though they might escape from the wound, during the operation, until the tumour was entirely removed; but that if it was necessary to protect them from cold, I had provided cloths and warm water in which lard would be dissolved for that purpose. 6th. That if adhesions existed I should use the knife for separating them, and not force them asunder with the fingers unless of a very recent character. 7th. That in the after treatment I should avoid, as much as possible, opiates and stimulants.

I then, accompanied by my medical friends, proceeded to the house of my patient: she was cheerful, and free from excitement, having prepared everything for the occasion that was thought necessary. The pulse still stood at 70; soft and compressible

OPERATION.

I placed my patient on a long narrow table covered with blankets, her head a little raised with pillows, and the abdominal parietes so situated that the best light the room afforded fell upon the part to be operated on; taking my station on the patient's right side, with a large scalpel, I severed the integuments from within a short distance of the ensiform cartilage, to the pubes at one stroke: at this time it was remarked, how extremely thin the integuments were immediately over the umbilical region, which formed the most prominent part of the tumour, being scarcely thicker than strong

paper. I now carefully cut through the peritoneum, at the upper end of the first incision nearest the sternum, sufficiently to introduce two fingers of my left hand, which I had no sooner done, than I met with an adhesion, but which must have been recent, as it gave way easily before the fingers. I now introduced the probe pointed bistoury, and, under the protection of my fingers already introduced, lest the abdominal viscera should be injured, I cut with the bistoury the peritoneum equal to the outward incision. At this moment, none, but those who have witnessed such a scene, could have any idea of the extent and formidable appearance of the operation—the incision from sternum to pubis over the bulky tumour could not be less than twenty-four inches (being eighteen when the parts were flaccid subsequently), perhaps as large an incision as ever was made in the living subject; the parietes of the abdomen rapidly retiring laterally, and the enormous tumour (as it were) springing forward, was sufficient to startle the coolest and most determined individual. The uterus was lifted up from its normal position, and lay flattened against the anterior, and inferior, part of the tumour; its right broad ligament expanded on, and connected with, the tumour, forming its pedicle. The uterus as well as the appendages on the left side were perfectly healthy; the pedicle was then secured by a strong ligature, and separated; the tumour being firmly attached to about three inches of the broad ligament. On separating the pedicle, which was of considerable thickness, it was found that the main ligature did not prevent the vessels (that passed through it to supply the tumour) from freely pouring out blood; and it therefore became necessary to take them up in separate ligatures, one end of each being brought outwards with the main ligature of the pedicle. I now passed my hand round the tumour in search of adhesions; three or four of very recent character presented themselves, which gave way to the slightest touch of the fingers, and required no scalpel for their separation, but on the upper surface of the tumour, higher than the umbilicus and on the patient's left side, an omental adhesion, spreading for some space on the tumour, shewed itself; this I separated with the scalpel, when a small vessel poured out blood freely, which I secured and cut the ligature off close. My friend Mr. W. C. Vaudrey had now held the tumour raised for some time, to facilitate my search for adhesions; when all appeared clear I placed my hands in the iliac regions, and assisted him in raising the huge mass fairly from the abdominal cavity, in doing which a considerable force was required as the pelvic portion of the tumour filled that cavity so completely, that it felt similar to the attempt of pulling off a well exhausted cupping glass, from some fleshy part of the body. Dr. Radford and Mr Vaudrey paid every attention to the patient and gave her a tea-spoonful or two of brandy and water, whilst I immediately but temporarily brought the parietes of the abdomen together; Mr. Nursaw and Mr Southam kept them in their position, and I continued to sponge the lower part of the incision, as long as any fluid shewed itself, which was chiefly the remains of the ascitic deposit slightly tinged with the little blood that had been lost in securing the vessels of the pedicle; long as this account may appear, the time consumed up to this, was only twelve minutes and a half, and (as I had no ambition of making it a bloodless operation) about fourteen ounces were lost rather more than in all probability would have been, in consequence of one of the ligatures missing its hold, but, after all, no more than (in my opinion) benefitted the patient afterwards. The integuments were brought together by nine stitches, and straps of adhesive plaister between each, with long straps over the ends of the cross straps; and two long pads of linen were laid on either side of the incision, and over all a stout bandage of some breadth. My patient was then carefully lifted into bed, about forty-five minutes from the commencement; cheerful, and complaining only of a pain about the last lumbar vertebræ and right iliac region, which I attributed to the extension of the pedicle during the operation, which, though as little as possible, it was *impossible wholly* to avoid. The subsequent treatment of the case will in a great measure be tabulated in order that every particular may be recorded, and yet in a manner that will occupy less space, and with less tautology than by any other means. Before the treatment is entered upon however, it will be as well to state some particulars respecting the tumour.

(To be continued.)

REVIEWS.

Commentaries on some Doctrines of a Dangerous Tendency in Medicine, and on the General Principles of Safe Practice. By Sir Alexander Crichton, M.D., F.R.S., Physician to the Emperor of Russia &c. Churchill. London.

We have been exceedingly pleased with this work. It contains a great deal that many physicians have forgot, and much that a great many never knew; for, it has been the fashion within the last five and twenty years, to eschew Galen and Hippocrates, to contemn Cullen and his school, to sneer at Good and his *sesquipedalia verba*, and to forget Young and Sydenham, and Fordyce, and Cheyne and Friend, and all the old and venerated Medici of ancient days, and to worship, in their stead, a host of French and German, and some few English adventurers in physic, who, like the Governor of Barataria, renowned Sancho, fancy that every thing they say or do is new, because they know not what was said and done, and better said and done, by their betters who preceded them. But before we touch upon the marrow of the work, let us ask Sir Alexander—and we put the query with a diffidence which we own we do not generally experience when immolating lesser victims on the altar of our criticism—has he ever seen, inquired into, or taken any pains to acquaint himself with that "species of modern necromancy" (by which he means mesmerism), so unceremoniously condemned in the following manner:—

> I might have hinted, for instance, at the jugglеries of a species of modern necromancy, which has found advocates and professors among regularly educated physicians of this and other countries; but I should as soon have thought it worth while to examine seriously the mysteries of the Jewish Cabbala, by which the truly learned Fludd, in the 16th century, explained physiology and the phenomena of nature, or to have attempted to account for the practice and conscientious conviction of Valentine Greatix, who, in the beginning of the 17th century, pretended to cure all diseases by the imposition of his hand, p. 10-11.

We ask this question, because we suspect from the tenor of these remarks that the doctor has never witnessed a pure case of mesmerism; or if he has, he has not displayed his usual impartiality and good sense. Mesmerism may, or may not be true, for ought we shall assume in this article; but we insist that this is not the legitimate mode of refuting a fallacy or exposing an imposition. Did the author forget, that without one solitary exception, every medicament, every drug, every remedy, every eccoprotic (to use his own language), owes its present position in the pharmacopoeia, to chance, to accident, in a word, empiricism? Phraates, the son of that Orodes, whose brutality to Crassus Plutarch records, attempted to poison his father with monk's bane, but the poison cured him of a dropsy. Paracelsus, seeking the Elixir of Life, discovered alcohol; Van Helmont, hartshorn; Glauber, the salts that go by his name; and Galvani, preparing soup for his wife, developed the principle of Galvanism. The same may be said of Jesuit's bark, of mercury, of antimony, of iodine, of valerian, of foxglove, of, in short, all our active remedies, and indeed of some of the common necessaries of life. A quaint writer informs us, that certain monks of Arabia, having observed that the goats which fed on the berries of the coffee shrub, evinced extraordinary powers of amativeness, and being interested in the experiment, tried them on themselves, and were so gratified by the results that they introduced coffee into general use. The Nauplians, says Swift, were taught to prune their vines, by observing that those bore best on which their asses had been browsing; and is it not more philosophical, more natural, and more in accordance with the amenities of life, to inquire first into the merits of a system, or virtues of a particular remedy, rather than to condemn either the one or the other on some preconceived theory? The Nauplians did not refuse to avail themselves of the process of pruning, merely because they had learned it from asses. The query simply is, did Greatrix, or did he not, perform the cures attributed to him? This is the first step in the procedure; if we are to credit the testimony of the Earl of Orrery, Mr. Boyle, the Earl of Ormond, and numerous other respectable witnesses, and we see no reason to doubt it; he did perform certain very extraordinary cures; is the *modus operandi* (of which, by the way, he expressed himself unable to give any account whatever) not worthy of investigation? "How were these cures effected?" "By imagination! solely by imagination!" replies Dr. Crichton; "Granted. *They are nevertheless cures!*"

This, we think, is the proper mode of reasoning, and not that dogmatic don't-contradict-me-hold-your-tongue sort of argument, which is too common in the profession, and which Dr. Crichton is old enough to recollect Dr. Moseley applied to vaccination, and he must have read, Guy Patin turned against antimony and all its preparations. And, to continue the parallel:—Was it not this haughty self-sufficiency, this terrible adherence to prejudice or preconceived opinions, which called for Fagon's defence of the Harveian theory of the circulation,* and compelled Fabri † to publish his apology for the use of the Peruvian bark? An apology for the use of the Peruvian bark! Think of that Dr. Crichton, and then ask yourself, if any one of the numerous fashionable demi-educated men who roll about their chariots in the West-end, or the ill-paid tropic-fried army surgeons who broil their livers away in an atmosphere of brandy and sunshine, would believe that such a book had been absolutely necessary? Has Dr. Crichton forgotten that Malpighi disinherited his heirs because they allowed blisters to be put upon him when

* It may, perhaps, subject us to the charge of mendacity, when we say that we saw a book written some fifteen years ago, we think by a Dr. Gordon, to prove the Harveian theory a delusion! As far as we remember it was a clever performance. Is not this another proof of the uncertainty attending all physiological speculations, or, if the word be offensive, facts?

† Fabri was a Jesuit, who distinguished himself by laying claim to the discovery of the circulation of the blood.

he was speechless? Or that Brissot was banished for bleeding in pleurisy? Or that it was once necessary to have the consent of the Privy Council before any of the Royal Family could be blooded?* Lord Kames says that in his time, it was common to swallow stones to aid digestion (this was by recommendation of the faculty), and tells an anecdote of Francis the First of France, which is not inapplicable here. In the days of Francis, the professors of the practice of physic were confined to the persons of the Jewish persuasion; he, therefore, applied to the Emperor, Charles the Fifth of Spain, to provide him with a Hebrew physician. The latter complied with his request, but sent him a doctor who had been converted to Christianity; but when Francis learned this, he dismissed him, on which Lord Kames remarks,—"As, if a Jew were to lose his skill on being converted to Christianity, why did not the king order his own physicians to be converted to Judaism?"

Sir Arthur Clarke on Consumption says,—"One physician (Stohl) attributes the frequency of consumption to the introduction of the Peruvian bark. Another (Morton) considers the bark an effectual cure. A third (Reid) ascribes the frequency of the disease to the use of mercury. A fourth (Brillonet) asserts that it is only curable by this mineral. A fifth (Rush) says, that consumption is an inflammatory disease, and should be treated by bleeding, purging, cooling medicines and starvation. Whilst a sixth (Salvadori) says it is a disease of debility, and should be treated by tonics, stimulating remedies, and a generous diet. Galen recommended vinegar as the best preventive of consumption. Dessault and others assert that consumption is brought on by a common practice of young people taking vinegar to prevent obesity. Dr. Beddoes recommended fox-glove as a specific in consumption. Dr. Parr found fox-glove more injurious in practice than beneficial." But we must desist here, for similar instances of diversity of opinion could be collected on almost every disease to which the human body is subject, and every fact that physiology has discovered; and to what end have we collected these facts? Simply because we are desirous of shewing not only to Sir Alexander Crichton but to our junior readers, the students of this vast metropolis, the "Folly† of Dogmatism;" and as we shall have occasion to follow up the argument when we come to consider the treatment of fever recommended by Sir Alexander Crichton, we shall now proceed *secundem artem*.

The following remark is judicious, and of its truth we entertain not the slightest doubt:—

At the moment I am writing these lines I am in my seventy ninth year, and having passed the greater part of my life in the active pursuits of the medical profession, I cannot believe, now that I have retired from general practice, that the freedom of my animadversions will be attributed to false ambition, or to any unworthy motive, but rather to the true one, namely, a sincere desire of rendering some service to an useful and a very difficult art.—p. 11.

Sir Alexander again very judiciously remarks:—

Medicine is a science of observation and discovery, the deductions from which are employed for the maintenance of health, and the elucidation and cure of diseases. Some of the facts which are collected by patient and correct observation, as well as those which are discovered by mere accident, are of so simple, clear, and unmixed a character, as to command at once a perfect unanimity of opinion concerning them. But others, (and these are unfortunately by far the most numerous) are of so complicated, unsteady, and fleeting a nature, as to be of difficult scrutiny, and to be differently seen and described by different individuals, and, consequently they do not serve the purpose of correct reasoning.—p. 12.

We pass over the remaining portion of the ntroduction, though there is scarcely a line which is not worthy of transcription, and proceed to what may be termed the subject matter of the book, or, as before remarked, the marrow. But yet we cannot avoid transcribing to our pages the following very acute and very happy remarks. After having stated, that man is doomed to depend for life and happiness on the exercise of imperfect rather than of perfect sciences, Dr. Crichton, thus writes—and how truly!—"Such is the case with the PRETENDED *sciences of government and legislation, of finance, of trade, commerce and political economy*. The doctrines of these highly-favoured and nobly rewarded sciences are as unsettled, hypothetical, and contradictory, as those of medicine; not merely because, as in medicine, many of the facts on which they are built cannot be proved to be true, or because they are complicated, changeable in their nature, difficult to be collected, or methodically arranged, but also, because the professors of such sciences are exposed to causes which tend at all times to disturb their judgment, and from which the physician is happily free, namely, strong and baneful passions arising from the lust of power, party spirit, and political hatred. Over these highly-honoured sciences medicine may boast of one advantage, with which its professors, as a body, may console themselves in their humbler path of life. The errors of their opinions and practice can only affect the welfare of one individual at a time, whereas the crude hypotheses and vagaries of an empirical statesman, law-giver, financier, or political economist, or of a board of trade, when carried into execution, may destroy the happiness of a whole nation at once, or, at least, seriously injure the interests of numerous classes of its inhabitants." p. 14.

Dr. Crichton thinks, that though the symptoms of diseases are generally understood, yet this knowledge is far from being so complete as is desirable; and in support of his opinion, instances affections of the brain, spinal cord, heart, liver, and digestive organs—"the true distinctive symptoms of which are by no means agreed upon." He hopes, however, that frequent and attentive *post mortem* observations may throw light not merely on the art of recognizing diseases, but of elucidating their nature. He is encouraged in his expectations by reflecting on what Laennec, Andral, Broussai, Pinel, Esquirol, Georget, Foville, and others have done for semiotics; but we believe this to be, in a great measure, illusory.

Dr. Crichton thinks, that a great obstacle to the proper understanding of the nature of diseases has arisen from the premature desire to explain them; but he does not deny that hypotheses have been, to a certain extent, convenient, if not useful.

It may startle many when I declare it to be my opinion that there is no such thing in nature as a proximate cause of any *complicated* disease, such as typhus, in which every function of the body is more or less deranged.—p. 18.

We do not, we own, understand this, neither does the following explanation quite obviate the obscurity:

The only true cause of the complaint is that which is foolishly called a *remote one*, being that which first disturbs the relationship between vitality and the physical forces which exert their power on our solids and fluids, and on a due balance between which health depends. In fevers, many of the earliest symptoms appear synchronously, and are by no means consequences of each other. They spring simultaneously from the first influence of the exciting cause. Afterwards, indeed, there follows a succession of causes and consequences, but none of them of so influential a character as to merit the appellation of a proximate cause of the disease.—p. 19.

Are we to understand by this, that Dr. Crichton considers "proximate cause" as a cause, or origin of, rather than the disease itself? The proximate cause of a disease we have generally understood to mean the disease itself: for example—yellowness of the conjunctiva, skin, constipation, with clay-colored fæces, &c., constitute, together, an abnormal condition of the system, which we call icterus, or jaundice. Does Dr. Crichton, then, mean to say that there is no such thing as jaundice? It is possible we have misinterpreted our author, or he has misrepresented his meaning; but, at the text stands, we own we cannot understand it.

We pass now from the Introduction, which is a lucid summary of the contents of the volume, and proceed to the "Commentaries" themselves.

The first, "On the Functions of the Heart and Arteries in Health and Disease," is extremely important, extremely interesting, and extremely valuable. We feel, in reading it, that we are conversing with a thorough bred physician—a man of theory, of knowledge, and experience. Justice is here done to one whose elaborate essay on the blood, forming the subject of the Croonian Lecture for 1809, has been well-nigh forgotten in the fanfaronade of new-fangled theories, which have little to recommend them but the position of their promulgators. We allude to Dr. Thomas Young—a name which ought to be hallowed by every physiologist. We present an imperfect summary of this chapter, referring the reader to the work itself for further information.

Dr. Crichton laments, that, after the lapse of more than two centuries since the discovery of the circulation of blood, there should be still some difference of opinion among physiologists of equal reputation, as to the true action of the arteries and capillary vessels; since, though the "force" on which organic movements depend is still a mystery, yet minute anatomy, chemistry, and experiment "are sufficient to settle the question."

En passant, we may remark, that this very subject is a good argument against the doctor for refusing to inquire into the truth of a "species of modern necromancy;" since, if what he thinks so obvious "modern physiologists of equal reputation" find involved in uncertainty, if not obscurity, how much more allowance should be made for the believers in mesmerism, who, to a man, pretend to offer no explanation of its *modus operandi*, but content themselves with stating what appear to be *facts?*

Until the publication of the Croonian Lecture of Dr. Young it was the generally received opinion "that the blood, after its expulsion from the heart, was propelled in the arteries, and especially in the capillaries, by a regular succession of muscular contractions and relaxations of these vessels, which were similar in kind, though not in degree, to the systole and diastole of the ventricles and auricles of the heart." p. 2. This doctrine, originating from Haller, the author contends was founded in an anatomical mistake, viz., that the middle coat of the arteries was muscular. More careful examination, however, has proved this opinion

* Sir Charles Searborough, in the case of Charles the Second, was the first who ventured to let blood without consulting the Privy Council. For his promptitude on the occasion the Council voted him one thousand guineas, but forgot to enforce their own resolution!

† See Glanvil's valuable work with this title.

erroneous; and behold the proofs! Admitting that the function of the arteries and capillaries consists in alternate contraction and relaxation, Dr. Young shewed by simple calculation that the motion of the blood could not be promoted by such action; for the contraction would *oppose* progressive motion by a repetition of mechanical hindrances, while relaxation would induce a similar effect by *distending* the parietes of the artery, and thus allowing more space for the volume of blood.

Every ramification or branch of the aortic system must be supposed to act in a similar manner; the length of the portions contracting and relaxing, necessarily varying with their diameters, and, consequently, with the length of the vessel requisite to receive the blood so propelled from one of a greater capacity.—p. 5.

Much of Dr. Young's reasoning was based on the experiments of Hales and Keil, and he argues "that the blood in the human arteries is subjected to a pressure from the action of the heart, which is measured by a column of seven and a half *feet*, whereas, in the veins the column does not rise more than six *inches*." p. 7. Keil proved this by comparing the quantity of blood which flowed in a given time from the divided crural artery and vein of a dog, and the quantity obtained from the artery, as compared with the vein, (the space of time allotted to each experiment being equal) was as seven and a half to three, and according to the experiment of Hales, the loss of momentum was equal to the pressure of a column of blood of seven feet.—p. 8. We cannot follow the author more closely for reasons which are too obvious to be mentioned, and we therefore quote the following conclusive passage and leave this part of the subject for the private investigation of our readers:—

Suppose the left ventricle to eject about an ounce and a half of blood (J. Müller says, two ounces) at each contraction, and that there are seventy-five such contractions, and consequently pulsations, per minute, it then follows, by the calculations of Dr. Young, that the mean velocity of the blood in the aorta, is 8½ inches per second of time; the velocity in each of the succeeding segments of the artery must of course be smaller in proportion as the joint area of the branches are larger than the area of the aorta or chief trunk. It must also be recollected that the aorta is already distended with blood, though not fully so, when the ventricle contracts. When this happens, it suffers an additional, though only a minute, dilatation. It is this sudden swelling of the artery which produces the pulsation, and which is transmitted with such celerity to the remotest capillary. But this is the mere motion of a wave or undulation of the blood. It is not a succession of muscular action in the artery. This wave, according to Young's accurate calculation, travels at the rate of *sixteen feet* per second; whereas the blood, even in the aorta, does not move forward at a greater rate than *eight inches* per second. Deducting this from the motion of the wave, it leaves about fifteen and a half feet per second for the real motion of the pulse; the pulse, therefore, being an indication of a mere wave or undulation of the fluid, has no more relationship to its actual progressive motion, than the waves which are formed by throwing stones in a river have with its actual current. It is as distinct as the undulations of sound are from the currents of air or of the wind: and, consequently, the rate of pulsation cannot be an index of the progressive motion of the whole mass of blood. pp. 9 and 10.

In the "Inquiry Continued," which is an appendix, or rather, extension of the first commentary, we are thus instructed by the following able *resumé*:—

Independently of the profound calculations and convincing arguments which are brought forward by Dr. Young against the hypothesis of an independent muscular action of the arteries, the conclusion he arrives at receives confirmation from many recent anatomical observations of Hildebrant, Bichat, Döllinger, Rudolphi, Hodgkin, and Bright. The two latter, eminent practical physicians and physiologists, concur in asserting that the middle coat of arteries, when examined with a good microscope, exhibits a different structure from that of muscles, inasmuch as the tranverse striæ, which belong to these last bodies, are totally wanting in the middle tunic of arteries; and Döllinger has shewn that the capillaries of the middle tunic of arteries are distributed throughout its structure in an arborescent form, while, in muscles, they form a net-work, which surrounds each fibre. This is in itself a strong argument; but the analysis of muscular fibre, and of the middle coat of the arteries by Berzelius, settles the matter still more completely, for in the tunic of arteries he could not detect a portion of *fibrine*, which is so abundant and essential an ingredient in muscles. Water abounds in muscular fibres as well as fibrine; whereas the middle tunic of arteries is comparatively dry. Muscular fibre, like fibrine, is soluble in acetic acid; the arterial coat is not so. The solutions of arterial fibre do not exhibit any precipitate by means of ferro-cyanites, nor by alcalies, which, however, would happen, did they contain fibrine.—pp. 19-20.

From these extracts it will be seen that we do not in any way incline to the theory of Haller, so ably, but erroneously, supported by Dr. Wilson Philip. But, as it is impossible here to give our reasons for this opinion, to the very valuable work of Dr. Crichton we must beg to refer the reader, who if he desire to acquire information, or if he seek only to renew knowledge, will find his time profitably expended, his perseverance amply rewarded, and his understanding vastly enlightened by even a cursory perusal; nor will he rise from the study of this commentary wearied and disgusted, but invigorated and gratified, for whatever it is useful to know, or pleasant to read, —whatever will guide him in practice, and enchain him in study, connected with the *vexata quæstio* of arterial action,—is here collected, arranged, collated, and descanted upon with temper, knowledge, and moderation.

We delay what we have to offer on the other commentaries to our next number.

Electrotype Manipulation, &c. 10th Edition: by Charles V. Walker.—George Knight and Sons.

This is a work by the clever secretary of the London Electrical Society, who professes to give, in Part 1, the explanation of the theory, and instructions in the art, of working in metals, by precipitating them from their solutions, through the agency of Galvanic or Voltaic electricity: and, in Part 2, a similar elucidation with respect to electro-plating, electro-gilding, and electro-etching, with an account of the several applications of electrotype in the arts. The little work is lucidly and cleverly written, liberally illustrated by wood-cuts, and neatly got up; to all those interested in the interesting subject it treats upon, we can strongly recommend it.

An Essay on Diabetes, by H. Bell, D.M.P., one of the Librarians of the Faculty of Medicine, of Paris. Translated by Alfred Markwick, late *Externe* to the *Hopital des Veneriens*, Paris, member of the Parisian Medical Society.

The Essay before us is a condensed, but still very comprehensive detail, of all that was known up to the time of its appearance, of that still not sufficiently understood disease, diabetes. During its perusal we were strongly reminded of an essay on the same subject by Dr. J. L. Bardsley, forming the article "Diabetes" in the "Cyclopœdia of Practical Medicine;" although with less display of learning, there is perhaps more practically useful matter in the essay before us. In making a few brief comments, we shall take the various departments of the essay in the order in which they stand. In the division of his subjects we think the author has rather complicated, than simplified, the study, by admitting so many varieties of the disease, as "diabetes mellitus, diabetes with fatty matter, ureous diabetes, and aqueous diabetes." Perhaps after all the old division of mellitus and insipidus would have answered every purpose, more particularly as their treatment is in a great measure analagous; and it is not yet clearly shewn but that they may be all one disease, differing only in degrees of intensity at different stages, and thereby taking upon themselves new characteristics like many other diseases.

In the history of this disease, the author falls into the same error as the Practical Cyclopœdian, Dr. J. L. Bardsley, in supposing that Hippocrates knew little or nothing of the disease; indeed Dr. J. L. Bardsley says, "*Hippocrates seems to have been altogether ignorant of this affection;*" a round assertion, which we venture to think can only have arisen from careless reading. The very paragraph quoted by our author disproves the assertion of both essayists. "*If the urine is aqueous and more abundant than the fluid taken, it is a sign that the food is not properly assimilated during the whole time this superabundance of urine persists.*" We would ask the question how much more do moderns know of this disease than what is here expressed? It is true that Hippocrates did not speak of saccharine matter, but this does not prove he knew nothing of the disease, any more than Sydenham, who is acknowledged to have known the disease well, and who is equally silent on the saccharine principles. The fact may be that it did not exist in the cases falling under the personal inspection of those acute observers: had it been a never absent symptom of the disease, no doubt Hippocrates, as well as Sydenham, would not have failed to have noticed it. It would be equally unjust to challenge the father of medicine with not knowing the disease, because he had not noticed the involuntary discharges of semen (maintained by Bardsley) as a symptom, or the smell of hay in the urine advanced by another (Dr. Latham) in which opinion he stands alone. The simple fact of balancing the ingesta with the egesta, is proof sufficient that Hippocrates, Celsius, Aurelianus, Demetrius, and Sydenham, if not acquainted with the name of diabetes, were no strangers to its phenomena.

To fully justify our remark on the author's unnecessary complication of the subject, we find on dipping further into the book, four-fifths of the whole are taken up with the particulars of one division, viz. *diabetes mellitus*, the rest being summarily passed over. The symptomatic portion is well deserving perusal, being in truth a *multum in parvo*. The following extract will afford an example:—

"*Diabetes generally commences in a very* slow and insidious manner, so much so, that at first its existence can very easily be overlooked. The first symptoms which attract the attention are, a feeling of lassitude, excessive indolence, dryness of the mouth, with a disagreeable taste, frothy and viscid saliva, reddening litmus paper: all the functions seem to be performed well, except that of sleep, which is frequently disturbed by the necessity of making water. After some time a sense of weight is experienced in the epigastrium, accompanied with heat, pain, and frequently with coldness of the hands and soles of the feet. The skin afterwards becomes arid, harsh to the touch; the hair on the head, and other parts of the body, grows dry, and falls off in large quantities; the mouth is clammy at first, then sometimes dry, red, and smooth; the tongue is covered with a thick mucous coating,

which becomes afterwards brown, and occasionally quite black. The angles of the lips become incrusted with dried mucus: the mouth is affected as in scurvy; the gums soft and spungy, bleed from the slightest pressure, and present ulcerations at the bases of the teeth, which loosen and fall out; the appetite progressively increases, and becomes at last quite voracious. Occasionally the patient loathes animal food, and seeks only that of a vegetable nature. Digestion is often laborious, and accompanied with eructations and pyrosis. There is constipation, the fæces are dry, and often without odour. Dr. Latham considers a hay scent, which is exhaled from the whole surface of the body, but chiefly by pulmonary transpiration, as characteristic of diabetes; but this phenomenon has seldom been observed by other writers, and I myself never could meet with it. Sometimes there is pain, at others only a feeling of weakness, in the region of the kidneys. The evacuation of the urine is at times very painful, and excoriations of the prepuce with phimosis and redness of the orifice of the urethra, have often been observed. This irritation about the orifice of the urethra is often a source of great annoyance to the patients, especially to females. Anaphrodisia is of most constant occurrence. Dr. Bardsley has noted in several of his patients involuntary seminal discharges, a phenomenon *which has been marked by no other observer.* It is not uncommon to remark cephalalgia, dimness of sight, impaired hearing, and at times total blindness. The sleep becomes short, uneasy, laborious, and disturbed at every moment by a constant want to pass water, and to satisfy the thirst, so distressing to the patient. After a certain time, these symptoms are followed by extreme weakness, lassitude, and considerable emaciation; the pulse at first slow and weak, rises progressively, fever takes place, and returns sometimes at periodical intervals, but most frequently in a very irregular manner. Œdema of the feet and legs follows, and sometimes general anasarca. This condition has even a moral effect; the patient becomes sad and dejected, and in the last stage cerebral symptoms arise, as coma, delirium and convulsions, phenomena which are soon terminated by death. There are two very important phenomena of diabetes, which must delay us a moment, they are *thirst* and *urinary secretion*, being in general the two symptoms of the disease which first draw our attention. When diabetes is fully developed, the thirst becomes incessant, in no other affection, polydipsia excepted, is it so intolerable, so inextinguishable; it is in general proportionate to the excretion of urine, the quantity of which may, in some cases, be enormous."

On the last paragraph we would remark that one case has fallen under our notice of perfectly developed diabetes mellitus, where thirst was scarcely ever experienced. In respect to Dr. Bardsley, two or three curious cases where although the egesta were considerably more than the ingesta, yet the individuals increased in weight many pounds, we think the explanation far simpler than that stated by the worthy doctor. There is often more knavery practised in hospital nursing, and with patients themselves, than medical men generally allow for.

We shall pass over the physical and chemical properties of the urine, with remarking, that it is a masterly condensation of opinions; there is nothing however, particularly new, with the exception of urea being present in diabetic urine, a fact now established. On the state of the blood, we find nothing but what has been advanced before. The progress, diagnosis, prognosis, etiology and nature of diabetes, are brief—but interestingly compiled, and worthy of perusal. This brings us to the treatment of the disease, in which, the author leaves us in the dark, to guess his own opinions, but freely advances the plans of others, and leaves the reader to select for himself which he prefers. In this manner he runs through blood letting, animal diet, opium, astringents, tonics, warm baths, and lastly, various drugs and chemicals that have been introduced from time to time, as specifics, by various individuals, the author concluding that the plan of treatment should be changed occasionally, and that a combination of means is safer than any single plan, and more likely to effect the object in view.

In respect to the treatment of diabetes, we are of opinion, that if veracious medical statistics could be obtained, we should soon arrive at better conclusions; but, unfortunately, we only see one side of the question: cures only, are recorded, whilst failures never find their way to the public. Dr. Clay, of Manchester, in his essay read before the British Association on diabetes, endeavoured to direct the attention of the profession to the effects of tinc. of sesquichloride of iron, and he then states that if the existing statistics are of any value respecting diabetes, the tonic or astringent plan, or both combined, have accomplished more cures than any other means.

On diabetes, with fatty matter, or chylous diabetes, our author is very brief. Citing a case or two from older writers, admitting the rarity and obscurity of the disease, he gives the following:—

"The details into which we have just entered, enable us to recognizine diabetes with fatty matter, the principles of diabetes mellitus, only in a less degree; that the urine has the character of being cloudy and lactescent, sometimes spontaneously coagulable, of possessing a specific gravity but little above the natural standard, and of becoming bright when treated by ether, and of furnishing a more or less considerable quantity of fatty matter. Instead of this fatty matter there may be a kind of oil, immiscible with the urine, which then remains perfectly transparent."

The treatment is analagous with mellitus. On diabetes with excess of urea the author is still more brief, and confesses it analagous with mellitus in a milder form, irritability of the bladder being a distinguishing symptom; lastly, aqueous diabetes, another mild form (in our opinion) of the mellitus, is considered by the author as a distinct disease. In plainer terms, if a patient be recovering from diabetes mellitus, his diminished malady must be classified under a new head, and treated as a distinct species of the disease. Luckily the author's treatment is so allied to those, good for the other forms of the disease, that the different nosology will not seriously interfere with the patient's convalescence. At the conclusion of the book is a most valuable list of authorities on the subject, which will be of great advantage to those who may wish to pursue further enquiries The essay is well calculated as a faithful guide to the opinions of various and numerous writers on the subject, and for those who may have neither time nor opportunity to search, will prove a treasure. The translator is also entitled to credit for the perspicuous style, and he appears to have done the author full justice.

Part 2. Price of the work in 3 vols., 25s.——EDWARDS, MILNE, *et* ACHILLE COMTE.—*Cahiers d' Hist. Nat.*—A Course of Natural History; Part 4, Zoology, 12mo.——DUJARDIN, F., *Nouveau Manuel de l' Observateur*—Complete Manual of the Microscopic Observer, 18mo. 10s. 6d.——RIENER *Species Géneral et Iconographie des Coquilles vivantes*—A Description of living shell-fish, comprising the Collections of Lamarck and the Museum of Natural History, with those discovered by recent travellers. (The work will form about 150 livns., each containing text and 6 plates.) 8vo. per livn. 6s.; 4to. per livn. 12s. (Livns. 80 and 81 have just appeared.)——VAUCHER, S. P., *Hist. Physiologique des Plantes d'Europe*—Physiological Description of European Plants, 4 vols. 8vo. 35s.——BECQUEREL, A., *Séméiotique des Urines*—Treatise on the changes of the Urine in complaints, 8vo. 7s. 6d.—CIVIALE, *Traité pratique sur les Maladies des Organes Génito-Urinaires*—Practical Treatise upon the Diseases of the Genito-Urinary Organs, 3 vols. 8vo. 21s.

*** The French works above announced, may be had through Dulau and Co., Soho-square.

MEDICAL MEMS. OF THE WEEK.

EXCISION OF THE SPLEEN AS A REMEDY. —Mr. Eagle, of Kingsland-road, gives an article recommending the tying the splenic artery or vein, or the excision of the spleen in various diseases "produced through the medium of unhealthy blood." He cites two cases of rabbits suffering under marasmus, with hydateds; the splenic artery was tied in the one case—the splenic artery and vein in the other. The first nearly doubled its weight within a month from the operation; the second weighed, when operated on, 2lbs. 4oz., and 18 days afterwards, 3lbs. 11oz. Mr. Eagle affirms the improvement to be owing solely to the tying process. The first rabbit was subsequently killed, and shewed, in common with other rabbits similarly operated on and destroyed, traces apparently of *cicatrized* tubercles. Mr. Eagle adds his assurance, that "firmly convinced of the omnipotent agency in those carriers of oxygen"—the spleen in the production of disease—"he will, if allowed, operate on every case of dangerous scrofulous or tuberculous cachexy, throw into the jugular vein, as directed by Dr. Blundell, a few ounces of blood, alone proceed to take up the splenic artery—a work of two or three minutes, at most!" *We* should scarcely imitate him.

THE PROVINCIAL MEDICAL ASSOCIATION. —IN its spiritless and unmeaning conduct, (says the *Lancet*); *in* the fast and loose manner it which it has played with the question of Medical Reform; *in* its senseless and sickening laudations of imbecile persons; and *in* the utter absence of that bold and commanding spirit which should characterise such a body; we had really thought—*from* all these circumstances—that such an association was an object of especial worth in the estimation of our twaddling contemporary—the *Provincial Medical Association*. But we were deceived, and we are glad of it. We rejoice to find that even that journal, which was published for the published for the purpose of sustaining the rottonest parts of ous medical institutions, employs its feeble efforts in condemning the conduct of an association which, really, is little else than a disgrace to the professional body of this country. Annual meetings, feasting, toasting, guzzling, complimenting, and puffing, form the chief features of that stupidly-managed society.—[The bad grammar is not the only remarkable position of this little paragraph of our expiring contemporary. ED.]

INFLAMED PROSTATE. When this occurs with abscess in and around it, says Sir Charles Bell, support the constitution by the common means. Soothe the local irritation by washing the passages, by means of the catheter and syringe, contriving that the stream shall gently play from the side hole of the catheter into the

sinuses. Be very careful (if the ducts of the prostate be enlarged) that the point of the catheter is not entangled in them, or in the abscess, if it open into the passage. In diseased prostrate Petit and Desault are indifferent to the breaking of the membrane with the catheter. Nay, an idea prevails that it is good to unload the varicose vessels! There cannot be a greater mistake. The abrasion fills the bladder with blood, and lays the foundation of ulcer, fœtid discharge, and increased irritation.

Reproduction of Atmospheric Air.—M. Thénard has submitted to the French Academy of Sciences a communication on the means of remaining for a long period in a limited quantity of air, by the absorption of the carbonic acid gas exhaled, and the renewal of oxygen in proportion to its consumption. That the carbonic acid gas exhaled, and which, in excess, becomes fatal, may be absorbed by lime, is a well known fact; but as it is necessary, in the purification of air, to replace the oxygen, which is the vital principle, as well as to get rid of the excess of what is injurious, the great object to be obtained in cases where, as in diving bells, it is important to make the same limited volume of air serve for several hours, is to produce oxygen with ease and certainty. M. Théoard proposes to employ oxygenated water, and has shown that not less than 375 times the volume of water of oxygen-gas may be compressed in this vehicle, and subsequently liberated as required. But to produce this result great care and and expense are necessary, and, when obtained, the difficulty of preventing the escape of the oxygen when not wanted for immediate use is also very great.

Nasal Hæmorrhage.—According to M. Negour this may always be stopped by raising the arm of the same side, as that of the nostril from which the blood flows.

The Use of the Microscope.—A microscopical discovery made during the present year, by Dr. Simon, of Berlin, consists in the detection within the small mass of sebaceous substance which collects in the follicles of the skin, and becomes darkened at its extremity, and to which we give the name comedo, or grub, of an articulated animacule of considerable size.

MEETINGS FOR THE ENSUING WEEK.

Octr. 17, Monday, Medical Societies of London, 8 P.M.
19, Wednesday, Westminster Hospital Medical Society, 8 P.M.
20, Thursday, King's College Hospital Society, 8 P.M.
22, Saturday, Mathematical Society, 8 P.M.

ADVERTISEMENTS.

Now ready, post 8vo,

FOOD, and its INFLUENCE on HEALTH and DISEASE; or an ACCOUNT of the Effects of DIFFERENT KINDS of ALIMENT on the HUMAN BODY. By MATTHEW TRUMAN, M.D.

"Every one ought to peruse it, especially those suffering from derangement of the digestive organs."—Church of England Quarterly Review. John Murray, Albemarle street.

Just Published by Whittaker and Co., Ave Maria-lane.

CRUVELHIER'S ANATOMY.

Now ready, Vol. II. (completing the work) forming Vol. VIII. of

THE LIBRARY OF MEDICINE; Comprising a Series of Original Dissertations, Arranged and Edited by ALEXANDER TWEEDIE, M.D., F.R.S., &c.

VOL. II. of CRUVEILHIER'S ANATOMY, Translated by Dr. MADDEN, and Revised by Professor SHARPEY, of University College. This volume contains a copious index, and complete the work. Post 8vo., price 18s., cloth lettered. Vol. I. just published, the same price.

*** The two volumes contain 1,232 closely but clearly printed pages, and upwards of 300 illustrations.

Also, lately published,

PRACTICAL MEDICINE. By Various Contributors. 5 vols. post 8vo., cloth, price 10s. 6d. per volume.

MIDWIFERY. By Dr. RIGBY. Post 8vo., 10s. 6d. cloth.

SPILLAN'S MANUAL FOR STUDENTS, &c.

18mo. price 3s. 6d. cloth,

A MANUAL of CLINICAL MEDICINE; containing directions for examining the sick, and illustrations of the connection between the symptoms of disease and the structural lesions on which they depend, with cases to serve as exercises in clinical analysis. By D. SPILLAN, M.D., Fellow of the King and Queen's College of Physicians in Ireland.

LAWRENCE ON THE EYE.

Second Edition, Revised, Corrected, and Enlarged, in one thick volume, price 21s. cloth.

A TREATISE on the DISEASES of the EYE. By W. LAWRENCE, F.R.S., Surgeon Extraordinary to the Queen; Surgeon to St. Bartholomew's Hospital, and Lecturer on Surgery at that Hospital; Surgeon to Bethlehem and Bridewell Hospitals, and late Surgeon to the London Opthalmic Infirmary.

MEDICAL AND SURGICAL WORKS.

Published by Simpkin, Marshall, and Co., London.

BINGHAM'S (Robt., F.R.C.S.) PRACTICAL ESSAY on DISEASES AND INJURIES of the BLADDER, Retention and Incontinence of Urine, &c. 8vo. 14s. boards.

BLUMENBACH'S MANUAL of the ELEMENTS of NATURAL HISTORY. Translated from the German, by R. T. GORE, M.R.C.S. &c. 8vo. 14s. boards.

BLUMENBACH'S MANUAL of COMPARATIVE ANATOMY from the German. With Notes, by W. LAWRENCE, Esq., F.R.S. Second edition, revised, with numerous Additions and Illustrations, by W. COULSON. 8vo. 14s. boards.

EDWARDS'S (H.M.) MANUAL of SURGICAL ANATOMY, containing a minute Description of the parts concerned in Operative Surgery, with the Anatomical Effects of Accidents, and Instructions for the Performance of Operations. Translated, with Notes, by W. COULSON. 18mo. 5s. cloth.

MARTINET'S MANUAL of PATHOLOGY, containing the Symptoms, Diagnosis, and Morbid Characters of Diseases, together with an Exposition of the different Methods of Examination applicable to affections of the Organs contained within the Head, Chest, and abdomen. Translated, with Additions, by Dr. QUAIN. Fourth edition. 18mo. 7s. cloth.

LECTURES ON THE MORBID ANATOMY of the SEROUS MEMBRANES. By T. HODGKIN, M.D.

VOL. I. ON THE SEROUS MEMBRANES. 8vo., 10s. 6d., cloth.

This Volume contains the Author's investigations respecting Cancer, Fungoid Disease, Melanosis, &c.; and, as appended subjects, Parasitical Animals, and the Pathological Indications afforded by Colour.

VOL. II. PART I. ON THE MUCOUS MEMBRANES. 8vo 12s. cloth. This Volume, which treats of the Gastro-pulmonary System, as far as the termination of the small intestine, comprises the subjects of Pneumonia, Phthsis, Gastro-enteritis, the Affection Typhoide of Louis and Fever.

London: Simpkin, Marshall, & Co.

TO MEDICAL STUDENTS. T. JONES, Medical Bookseller, 91, Aldersgate Street, has on hand a large Collection of Second-hand and New BOOKS, which he offers at prices worthy the notice of Students, also, a complete Set of LANCET to 1837, in 27 vols., published at £28, for £6 6s.

MR. COLES continues to Manufacture his improved TRUSSES, the merits of which have been universally applauded. The increased ease and security they afford sufficiently establish their superiority over all previous inventions, the mechanism of the pads is such that they yield to the various positions of the Body, most effectually securing the parts under the ordinary exertions of Coughing, Walking, or Riding.

A single post letter, containing the opinions of Sir A. Cooper, Bart., and many eminent Surgeons, together with a description of the Truss, and instructions for giving an Order, may be had at the Manufactory, 3, Charing Cross.

ROYAL COLLEGE OF SURGEONS IN IRELAND.

WINTER SESSION COMMENCING OCT. 31.

ANATOMY AND PHYSIOLOGY	Dr. Jacob.
DESCRIPTIVE ANATOMY	Dr. Hargrave, Dr. Hart.
SURGERY	Dr. Wilmot, Dr. Porter.
PRACTICE OF MEDICINE	Dr. Benson, Dr. Evanson.
CHEMISTRY	Dr. Apjohn.
MATERIA MEDICA	Mr. Williams.
MIDWIFERY, AND DISEASES OF WOMEN AND CHILDREN	Dr. Beatty.
MEDICAL JURISPRUDENCE	Dr. Geoghegan.
HYGEINE	Dr. Maunsell.
BOTANY	Dr. Bellingham.
NATURAL PHILOSOPHY	Dr. Apjohn.
COMPARATIVE ANATOMY	Dr. Jacob.

Dissections under the superintendence of the Professors of Descriptive Anatomy, and the Demonstrators, Mr DILLON, Mr. ELLSON, and Mr. LABATT.

C. O'KEEFE, Registrar.

DR. STEGGALL continues his LECTURES and EXAMINATIONS for the College of Surgeons and Apothecaries' Hall, also for the other Medical Boards. His fees are for an unlimited period, consequently pupils would derive increased benefit by entering at the commencement of their studies, thus obtaining a tutor to direct them during their entire residence in London. Dr. S. is quite willing to guarantee their success. Hours of attendance, from Ten till One, a.m., and Six to Nine p.m., in Chambers, at No. 17, Bloomsbury-square.

NOTICE TO INVENTORS.—The OFFICE for PATENTS OF INVENTIONS AND REGISTRATION OF DESIGNS, is REMOVED from No. 62 to No. 14, Lincoln's Inn Fields, where all business relating to the securing and disposing of BRITISH and FOREIGN PATENTS, Preparation of Specifications, Drawings of Inventions, is expeditiously and economically effected.

Also, REGISTRATIONS under the New Consolidated Copyright and Designs Act 5 & 6 Vict. cap. 100.

A Prospectus, containing much useful information, may be obtained, and references to an Alphabetical List of Patents and Registrations made, on application to Mr. Alexander Prince, 14, Lincoln's Inn Fields.

PHILOSOPHICAL INSTRUMENTS.

WARD'S CATALOGUE of CHEMICAL and PHILOSOPHICAL INSTRUMENTS is now ready for distribution, gratis. It is illustrated by 300 Woodcuts, and every article (above 2000) is priced, the Weight under 1 oz. All letters to be paid.

THE CHEMICAL CATALOGUE of PURE TESTS and RE-AGENTS is nearly ready.

Agent for Griffin's Cheap Apparatus and the German Porcelain, JOHN WARD, OPERATIVE CHEMIST, 79, Bishopsgate Street Within.

CURVATURES OF THE SPINE, DEFORMITIES OF THE LIMBS, &c. Mr. AMESBURY'S PRIVATE ORTHOPEDIC ESTABLISHMENT for the PREVENTION, RELIEF, and CURE of CURVATURES of the SPINE. The time required for restoration of the Spine, in curable cases, varies from three to twelve months. In very bad neglected cases a longer period is necessary. The health and strength are greatly improved by the treatment adopted. In cases of In-knee and Out-knee, In-ankle and Out-ankle, the limbs are commonly restored to their natural line in a few days, a longer period, however, is necessary to complete the cure. Particulars may be obtained by application to Mr. AMESBURY, at his Residence, 12, Devonshire-street, Portland Place, London. For Illustrations see his

PRACTICAL REMARKS on DEFORMITIES of the SPINE, CHEST, and LIMBS, STIFFNESS and WEAKNESS of the JOINTS, MUSCULAR CONTRACTIONS and MUSCULAR WEAKNESSES, Partial and General. 4to. £1. 11s. 6d. Published by LONGMAN & Co., Paternoster Row, London. By the same Author,

PRACTICAL REMARKS ON FRACTURES of the TRUNK and EXTREMITIES, with Plates and Cases, 2 Vols. 8vo. £1. 5s.

J. WALTERS,

ANATOMICAL MACHINIST, &c., 16, MOORGATE ST., LONDON,

BEGS to call attention to the under-mentioned of his contrivances, which have met with the approbation of the most eminent surgeons, and will be found to combine many advantages.

THE HYDRO PNEUMATIC ENEMA SYRINGE.

This newly invented instrument is very much superior to any at present in use, on account of its simplicity, great portability, and durability. It is in itself Reservoir and Syringe, less than half the size of any others that hold the same quantity of fluid, and gives a continuous jet of any force required, and free from air.

THE ELLIPTICAL SPRING CRUTCH.

By the construction of the air-pads of the prongs and of the central joint, the greatest freedom of motion is allowed, without that distressing numbness of the arm, produced by crutches of every other description.

THE ELASTIC LACED BANDAGES,

For Varicose Veins, &c., are light and durable, allow the perspiration to pass freely through them, and, from the thinness of the material, cause but little additional warmth. The price is much less than that of any other equally well made. Directions for measuring will be forwarded on application.

THE NEW HIP-JOINT SPLINT

Has been used in many cases, and can be confidently recommended as the best hitherto contrived for diseases of this joint.

CHARLOTTE STREET SCHOOL OF MEDICINE.

Lectures commenced Oct. 1st.

PERPETUAL to the ANATOMICAL and SURGICAL LECTURES, DEMONSTRATIONS and DISSECTIONS, 10 Guineas.

To all the Lectures necessary for College and Hall, 30 Guineas.

The whole expense of Professional Education necessary for College of Surgeons and Apothecaries' Hall, including all the Lectures and Three Years Hospital Practice, £55.

The Three Years Physician's Hospital Practice, also serve for passing, as Licentiate, the College of Physicians.

The above Lectures recognized by the London University and all other Medical Boards.

N.B. The expense of Lectures required by College and Hall, to be attended first winter Session—Anatomical Lectures and Demonstrations, 5 Guineas. Materia Medica, 3 Guineas. Chemistry, 4 Guineas.

Registration of Pupils commences at Apothecaries Hall, Oct. 10, and terminates October 26.

Apply to Mr. DERMOTT, 15, Charlotte-street, Bloomsbury.

ORIGINAL MEDICAL GLASS AND FIXTURE WAREHOUSE.

HAWKE, late ANSELL & HAWKE, of No. 8, Great Queen Street, Lincoln's Inn Fields, begs to inform Gentlemen commencing or altering in the above Profession, that they have a large assortment of Drawers, Bottles, Jars, and every requisite for completing Shops or Surgeries, on the most moderate terms. Most satisfactory references can be given as to style and quality. Plans and Estimates furnished, free of expense.

Valuation of Stock and Fixtures.

MEDICAL.—HIGHLY FAVOURABLE OPPORTUNITY.

DESIRABLE FREEHOLD PROPERTY situate in the town of CLUN, in the county of SALOP. To be Sold by Auction, by Edward Mason, at the Buffalo's Head Inn, in Clun aforesaid, on TUESDAY, the 11th day of OCTOBER, 1842, between the Hours of FOUR and SIX o'Clock in the Afternoon, subject to such Conditions as shall be then produced,—all that substantial Stone built Mansion or Dwelling House, situate in the town of Clun, in the County of Salop, now in the occupation of Mr. Cullis. The ground floor consists of Entrance Hall, Kitchen, Drawing and Dining Rooms, with nine suitable Bed Chambers and Attics above. Attached to the House, is a large and productive Garden,well stocked with Choice Fruit Trees, a spacious Court Yard, and a newly erected Stable, Coach House, etc. and the whole is enclosed with a Stone wall.

Persons desirous of insuring to themselves a comfortable residence, have here the opportunity, the House being in complete repair, and the Premises in every respect convenient, the present Proprietor having expended much time and money to make the whole fit for the residence of a genteel family.

A Purchaser may be accommodated with the present Proprietor's extensive and respectable practice as a Surgeon and Apothecary.

POSSESSION will be given at Lady-day next.

The Proprietor, Mr. CULLIS, will shew the Premises, and further particulars may be obtained on application to Mr. THOMAS GRIFFITHS, Solicitor, either at his Office in Bishop's Castle or Clun.

Sept. 1st, 1842.

SOLUT. MAGNES. BICARB.—Dr. WILKINSON, of Bath, whose well-known familiarity with Practical Chemistry entitles his opinion to respect, says,—

"A bottle of the Fluid Magnesia of Sir James Murray's sent to me for Analysation by a Chemist in this Town, gave me Seven Grains of Magnesia and *Three of Sulphate of Soda* to the ounce, whilst yours yielded Seventeen Grains of PURE MAGNESIA to the ounce. I conscientiously bear testimony to the correctness of the above results.

(Signed) "C. H. WILKINSON, M.D."

"Dated October 23d, 1840."

To Mr. C. DINNEFORD, Bond-street, London.

The above conclusive testimony is further corroborated by PROFESSOR BRANDE, of the Royal Institution.

DR. PARIS, author of the Pharmacologia, and Mr Morgan, of Dublin, who also examined and reported on Sir James Murray's COMPOUND.

It has also received the sanction of SIR HENRY HALFORD, Bart., President of the Royal College of Physicians, and the most distinguished Members of every branch of the Medical Profession.

Sold in Jars (for Dispensing only) containing 5lbs., at 5s. 6d. each, by the usual respectable Wholesale Houses, or direct from the Proprietor.

HÆMORRHAGE, internal and external, other baffles the Skill of Medical Men. SIR B. C. Brodie, Dr. Chambers, Dr. J. Johnson, Professor Mayo, Mr. Guthrie, and other high authorities, have for Years strongly recommended and exhibited, with all the greatest success, the CHEVALIER RUSPINI'S STYPTIC. Speaking of Hæmoptysis, DR. CHAMBERS says, "Giveone drachm of Ruspini' Styptic every three hours;" SIR B. C. BRODIE, also, "Apply Ruspini's Styptic," MR. GUTHRIE, "If the bleeding be obstinate you may suppress it by Ruspini's Styptic," DR. JOHNSON, "The Styptic possesses extraordinary powers in arresting Hæmorrhage;" PROFESSOR MAYO, "Of all the Styptics with which I am acquainted Ruspini's is the most efficacious;" together with numerous other eminent recommendations.

It is Prepared and Sold Wholesale and Retail, at the Depot, C. COLLINS, 54, PICCADILLY, to be had also at the Wholesale Houses, and Retail at all the Druggists in the Kingdom.

MEDICAL LATIN.—GREGORY & CELSUS. HAMILTONIAN SYSTEM, 122, Regent Street. The attention of Medical Students is directed to the fact, that with scarcely any previous knowledge of Latin, they can, in a FEW WEEKS, be rendered competent to pass their examinations. The Hamiltonian System of Learning Languages has been pronounced by the Edinburgh and Westminster Reviews, one of the greatest improvements of the age. Classes are now forming. Also Private Tuition on moderate terms. Apply to Mr. LANGMAID, 122, REGENT STREET.

TO WATER-COLOUR PAINTERS.—MILLER'S GLASS MEDIUM. It is well known that some preparation for giving brilliancy and depth to Water-Colour Painting, and for enabling the Artist to repeat his touches without disturbing the colours already laid on, has been long sought after; this new vehicle possesses all these advantages. When mixed with the colours it has a most brilliant effect, and will preserve delicate tints unimjured, in durability it will approach nearer to Oil Painting than anything hitherto in use.—MILLER'S Artist Colour Manufactory, 56, Long Acre, London.

IMPILIA BOOTS (Patent) having a preparation of horsehair mechanically and imperceptibly compressed between the inner and outer sole. Boots and Shoes on this principle repel the wet and absorb the perspiration, are elastic and comfortable, and no cold or damp can penetrate them. For tender feet or corns they are perfectly luxurious. The wearer may tread the roughest pavement without inconvenience, they do not creak, and are equally cheap and more durable than those made in the ordinary way. Manufactured by F. GULLICK, 44, Warwick-street, Regent-street. Respectable Bootmakers in each town may have licenses on moderate terms on application to Josiah Towne, Esq., Knightsbridge.

TESTIMONIALS.

From J. G. Andrews, Esq., St. Helen's place, President of the Royal College of Surgeons.

I have worn for some time the new patent boots, called Impilia, with much comfort and satisfaction, I find the boots possess great elasticity, evenness of pressure, and I am enabled to walk a greater distance without inconvenience.

J. G. ANDREWS.

April 20, 1842.

From Anthony White, Esq., Parliament-street, one of the Council, and late President of the Royal College of Surgeons.

I can with much satisfaction recommend to the public the boot or shoe which is denominated Impilia. Its peculiar advantages over all other boots or shoes are, that it is impermeable to wet and damp, and always gives an agreeable and constant warmth to the feet, is also elastic, and is admirably adapted to tender and crippled feet from gout or other maladies.

ANTHONY WHITE.

April 6, 1842.

From Dr. Paris, of Dover-street, London.

I have examined and worn with comfort and satisfaction shoes constructed with intermediate soles of felt, to which you have bestowed the name Impilia. They undoubtedly possess an elasticity and capacity of adaptation to the form of the foot not possessed by ordinary shoes, and they have the rare merit of not creaking. They are, moreover, warm and dry.

J. A. PARIS, M. D.

From Dr. Roots, Russell square, London.

Dear Sir, I have now worn for some time a pair of boots with intermediate soles, which you term Impilia. They are admirably adapted for the ease and comfort of tender feet, and the elasticity of their tread is very pleasant. I can with confidence recommend them for general use, while for medical men they possess the very rare advantage of not creaking, and consequently are desirable in a sick room.

H. S. ROOTS, M. D.

W. Baker, Esq.— April 2, 1842.

From Dr. Hodgkin, Lower Brook-street, London.

Having not only examined, but put to the proof of experience, the patent soles invented by my friend Wm. Baker, M.R.C.S., and termed Impilia, I have no hesitation in saying that they are a very decided improvement on the common method of construction. They are not only much more agreeable to the sole of the foot, but promote a warm and uniform temperature as well as freedom from damp, whether entering from without or derived from the feet.

THOMAS HODGKIN, M. D.

30 4, 1842.

From John C. Taunton, Esq., M.R.C.S., 48, Hatton-garden.

I have worn with satisfaction the boots with the intermediate soles of Impilia. They are worn with more comfort, adapt themselves better to the form of the foot, and are impervious to wet.

JOHN C. TAUNTON.

May , 1842.

London: Printed and Published by JAMES ANGERSTEIN CARFRAE, 10, Wellington Street North, in the Parish of St. Paul, Covent Garden, Westminster, in the County of Middlesex. October 8th, 1842.

AGENTS.—Maclachlan & Son, Edinburgh; Simms & Son, Bath; Wilmer and Smith, Liverpool; Fannin & Co., Dublin.

THE MEDICAL TIMES

A Journal of English and Foreign Medicine and Medical Affairs.

No. 161. Vol. VII. LONDON, SATURDAY, OCTOBER 22, 1842. PRICE FOURPENCE. Stamped Edition, 5d.

For the convenience of Subscribers in remote places, the Weekly Numbers are re-issued in Monthly Parts, stitched in a Wrapper, and forwarded with the Magazines.—Orders for the Stamped Edition (10s. 10d. per Half-year, Post-free in advance,) are received by any Book-seller or Newsman, or may be directed to J. A. Carfrae, Esq., at the Medical Times Office, (late Lancet Office), London.

SUMMARY.

ON THE LAWS OF THE DEVELOPMENT OF ORGANS; OR, TRANSCENDENTAL ANATOMY APPLIED TO PHYSIOLOGY.

By E. R. A. SERRES, Member of the Institute, of the Academy of Medicine, Professor to the Museum of Natural History, Paris, &c., &c., &c.

SUMMARY.—*Effect of the Microscopic Researches of Lewenhoeck and of Hartsoecker.—Idea of the original enclosure of the germs; Malpighi; his Researches upon the Ovum; his ideas upon the Development of the Adipose Tissue, &c.—Boerhaave; his doubt upon the ideas of the Histologic Homogeny of Ruysch and of Malpighi.—The Nervous System considered as the generator of all the other tissues; Inconsistencies of the Supporters of the Centrifugal Theory of Developments.—School of Haller.—Physiology Detached from Anatomy as a Distinct Science; Works of the Anatomists of this School in Comparative Organogeny.—Haller, at first for the Theory of Epigenesis, and afterwards for that of Pre-Existences.—The Heart the Primary Generator of the other Organs.—The Theory of Centrifugal Development based upon the Physiology of the Adult.—State of the System of pre-existences as represented by Bonnet and Haller.—Needham attacks the Hypothesis of the Existence of germs; his Experiments upon the Formation of the Infusoria; occult forces admitted by him.—Wolf: analogy of his occult forces, with those admitted by Needham; opposes the creative action of the Heart; his labours upon the Development of the Sanguiferous system; idea of the successive Formation of Organs—Theory of Organic Evolution established by Haller.*

SUCH, as I represented in my last lecture, are the grand views which have been developed since the commencement of the theory of epigenesis. But unfortunately at the period when science assumed this new course, the system of organic pre-existences sprung up to retard its progress; thus was organogeny arrested in its most important hour by the substitution of an obscure and entirely artificial philosophy for that of nature. The origin of the theory of pre-existence was owing to the abuse of the early microscopic researches of Lewenhöeck and Hartsoecker. Astonished at the results furnished by the microscope, the imagination of physiologists exaggerated still more its power. At first perceiving the entire animal in the ovum, in its last stage of incubation, they then imagined its presence in the ovule before conception; and finally throwing aside the clogs of observation, Swammerdam and Malebranche conceived the pre-existence of germs, and their enclosure, the one within the other, since the commencement of time. This gigantic idea met with a success unequalled by the discoveries of Galileo and of Newton. But how incredible that the whole of the past and future generations should have been enclosed within the ovary of Eve, our common mother; and that however invisible the embryo may be within the ovum, it is not the less an exact repetition of the adult man! Embryogenic researches hence presented but slight interest. For what purpose, said people, waste one's time in labours of so difficult and delicate a nature, if the youngest embryo presents but the miniature of the perfect animal? What can science gain from this study of infinitely minute productions, if such beings are nothing but what nature shews us on a large scale at another age in man and animals? What answer could be given to arguments apparently so decisive?

This abandonment of embryogeny was still more effectually brought about by the researches of Malpighi with the microscope, while Haller, at one time a partisan of epigenesis, at another of pre-existence, eventually declared himself for the latter system. A remark which I have already made, and which here again presents itself, is, that the primitive principle of organogeny was the indivisibility of life, and consequently the unity of its gradation in beings endowed with it. Organized nature was not separated into two kinds, the vegetable and the animal, but was considered as but one, and undivided, although endowed with various degrees of perfection. Malpighi, however, adopted new views, and stood forth like a giant from the host of embryogenists who preceded or have followed him. Commencing the study of organogeny, by the consideration of vegetable life, he applied the knowledge thus gained to the first formation of animals. Taking up animal embryogeny at its primary starting point, he compared its first formations with those of the vegetable kingdom, of which they are but an imitation, and was thus led into a field of discoveries, the full value of which he himself did not appreciate. Before his time, although the existence of the *cicatricula* had been frequently pointed out in the ovum, no one had traced in its composition the first outline of the embryo. It was reserved to Malpighi to overcome this task. And with what clearness did he trace the arrangement of the *blastodermic* membrane! How beautifully did he define the first appearance of the vertebral column, together with that of the nervous system, and also what was still more difficult of discovery, that of the blood-vessels! The creator of organogeny, as Harvey had been of ovology, he referred these first formations, anterior to the appearance of the heart, to a *creating* action in the tissues, which had the power of repeating itself in vegetables and the inferior animals, and which in the superior animals, and man, presides over the molecular life of formation during the whole duration of existence. It is this power, the nature and essence of which are unknown to us, which we so often hear of under the names of *plastic force*, of *nisus formativus*, or of *organic vital properties*. These facts, however, remained unproductive in the mind of Malpighi, prejudiced as he was in favour of the theory of pre-existence. Centrifugal development being one of its maxims, Malpighi laboured to prove that the adipose system becomes propagated from the omentum to the other various parts of the body, that is to say, from the centre towards the circumference. Scarcely, however, had he emitted this general idea, when studying the formation of the adipose vesicles which compose the system, he found them developed from the circumference towards the centre, a fact since demonstrated by M. Raspail. The difference in importance, as a product, between an adipose vesicle and an ovigenous vesicle of de Graaff, appears immense; but not so in considering the mode of formation. When then Malpighi compares this ovigenous vesicle to a glandular body, when he makes it secrete the ovules in birds, not only does he make an immense step forward, but he overthrows the idea of the original enclosure of the germs, for it is clear that if the ovules are secreted by the ovigenous vesicle of de Graaff, their pre-existence is illusory. Here then, as every where else, the observations adduced in support of the centrifugal theory, went in reality to prove the truth of the centripetal law of development.

As in the theory of epigenesis, the successive formation of parts constitutes one of the precepts of organogeny; so in the theory of pre-existence this notion was rejected, since every organ was presumed to be developed at the same time, and from this abandonment naturally resulted that of the study of the laws of formation and of development. But as a kind of compensation, the system of homogeny then took a new flight. During nearly half a century all the efforts of anatomists were directed towards the discovery of a primitive tissue, of which all organisms were considered to be merely modifications. Hippocrates said that there was but one disease, of which all other maladies were simply modifications. Plato and Aristotle in like manner acknowledged but one animal, whose various metamorphoses produced all other animals. It was to prove the reality of these abstract notions that the anatomical philosophy of that period chiefly applied itself.

The fibrous tissue, the most easily observable in organs, was the first supposed generator of the others; the vascular tissue requiring the greatest difficulty in its preparation, needed the skill of a Ruysch for its demonstration. Lastly, it was reserved for the sagacity of Malpighi, in microscopic observations, to discover the *acini*, or small glandular follicles, in the intimate structure of the organisms. Glandular, fibrous, and vascular homogeny, were, however, never demonstrated, but new views and relations upon the various analogies of tissues and of organs were developed; views which eventually led to the organic *homology* of Vicq-d'Azir and of Spix, the system of organic tissues of Bichat, and the theory of analogues of Geoffroy Saint Hilaire.

In the midst of the animated discussions accompanying these researches, Boerhaave at first decided in favour of vascular homogeny, which favoured his theories, since so celebrated, especially that of pathological inflammation. The subsequent discovery by Malpighi of the early appearance of the spinal marrow, induced this acute observer to suppose, like other homogenists, that all parts were originally nervous, and that they all radiated at the commencement from the centre towards the circumference; thus was the hypothesis of centrifugal development, which seemed to have been for some time abandoned, once more revived. Under this state of things arose the school of Haller. Among these contradictory opinions it became necessary to shape some positive course in the study of organic formations. Unfortunately the influence of Haller was thrown into the wrong scale. On reading attentively the lectures of Boerhaave, and their able commentaries, we readily perceive that the science of organisms had assumed a new direction. Hitherto the *use of parts* as adopted by Galen had enjoyed but a secondary place in the study of the organic apparatus; this accessory portion suddenly became the essential and fundamental portion, around which all others were centred; *physiology*, in a word, became separated from anatomy as a distinct science. It became detached, not as a special science limited to man, but as a comparative science, that is to say, that it took man as the term of relation, and all animals as objects of comparison and subjects for experiment. With data apparently so simple, Haller founded a new science, and upon bases so enlarged, that his work has remained unaltered to the present day; it is a perfect encyclopædia of the natural sciences applied to the study of the functions of man. With reference to comparative organogeny, one of the first acts of this experimental school was to efface from science the chimerical organisms, introduced by centrifugal development. Thus for the purpose of carrying the adipose fluid from the centre towards the circumference, an order of adipose vessels had been invented, in the same way as neurolymphatic vessels had been created for the centrifugal circulation of the vital and animal essences, the existence of which, according to Malebranche, could not be doubted by any one. These vessels were, however, completely rejected, inasmuch as they could not be discovered by dissection nor by experiment.

By aid of this severe reasoning in the interpretation of facts, Haller refuted the theory of organic pre-existences, although previously bred up in this doctrine. He formally declared himself for epigenesis, which appeared to him abundantly evidenced by the observations of William Harvey, of Malpighi, Lancisi, Maitre-Jean, and by the experiments of Réaumur and Trembley upon animal regeneration. It was at this period of his scientific life that he laid the foundations of his grand theory of arrest of development.

By what fatality then was Haller drawn into the opposite opinion? What could have passed in his mind to induce him to conceive the entire animal within the ovum? To admit in its developments but an elongation of parts—to see the entire heart in its primitive canal—to refuse the evidence of his senses, when he perceived the auricles and ventricles superadded to this canal, and its muscular fibres appearing where they had not previously existed. How could he, after these facts, consider the embryo a repetition of the perfect animal? How, by this theory, explain the existence of certain organs in the embryo, and their disappearance in the adults—of the new intestinal canal which, in insects, succeeds the primitive one—of the bronchi which are replaced by the lungs—of the Wolfian bodies which precede the genital organs? How explain the regeneration of the head, the tail, the paw, and the reproductive organs, which had been demonstrated by the experiments of Reaumur, of Trembley, and of Mortimer? Not to dwell unnecessarily on these organogenic problems, Haller arrived at the conclusion, against his first sentiments, that epigenesis is impossible—that there is no part of the body of the animal made anteriorly or consecutively to the others; that in fact all parts are formed at the same time. He rejected even, what his predecessors and himself had before observed, the *successiveness* of organs. These authors, he pretended, merely wished to say that such parts are visible in the embryo while certain others are not. The whole is, however, *pre-existent* in the part. The animal is contained in the embryo, the embryo in the ovum, the ovum in the ovule, and all the ovules were enclosed in the ovaries of the first females. This was the principle at which Haller arrived with respect to the development of organisms. From the moment that he admitted developments to have simply the effect of rendering visible parts which previously were not so—that he reduced formations to an elongation, or a spreading out of the organisms—he created a necessity for imagining an active power capable of producing these results. Too much of a physiologist to admit an occult power, a visible force became requisite; the heart offered this condition in the fœtus and the adult; he, therefore, attached his theory to this organ, and supposed its existence and its action at all periods of embryonic life.

From data such as these, the system of pre-existences became the almost general belief of physiologists. Founded on false analogies, centrifugal development became the primordial law of developments, and the formation of the organisms was attributed to the heart. In fine, from this combination of errors, the physiology of the young embryo was put almost on a level with the physiology of the perfect being. Every thing is mutually dependent and interwoven in the sciences of anatomy and physiology. The functions necessarily attend the organs; these being declared unchangeable, the functions cannot be allowed to vary. As they are in the adult, so ought they to be in the young embryo, since the embryo is considered but a diminutive adult. Such, then, we will consider them. Now, who can hesitate to acknowledge that in the adult the circulatory movement is centrifugal? Who can doubt, but that in the infant, growth depends on the continuous transport of the sanguineous fluid from the centre towards the circumference? Who does not know that aliments introduced into the intestinal canal are converted into chyle, which from this central point is distributed to all the organisms? Who does not know, that to bring intra-uterine on a level with extra-uterine physiology, so many embryogenists have advanced that the fœtus is nourished by the waters of the amnios? Lastly, who will deny that the nervous action has its centre in the cerebro-spinal axis, and that it radiates from this central point to the periphery of the nervous system? These are common but no less positive notions. Are they, however, applicable to the young embryo and to organisms in the course of formation? This is the key of the question. The advocates of pre-existence assert the affirmative; but all embryogenic facts and observations lead us to the opposite conclusion. It is then, in these facts and in their rigorous interpretation that the theory of epigenesis finds its support; here it is that it is positively assured of victory.

Such was the system of pre-existences supported by Bonnet and Haller. This system seemed to be based upon two grand hypotheses. The one, in some measure borrowed from Leibnitz, was relative to the germs; it supposed these miniatures of vegetable and of animal bodies floating in space, circulating quietly in the various organized bodies until meeting with the mould in which they are to become developed; thus commenced the abandonment of the indefinite enclosure of these bodies. The second hypothesis related to embryogeny; the heart and its impulsive action replaced all the occult forces of the ancient physiologists, and the presence of this organ was imagined at all periods of animality. Of these two hypotheses, the first, entirely metaphysical, exercised but little influence over the subsequent course of anatomy; the second, which was perfectly physiological, became, on the contrary, the basis around which animal embryogeny was constructed. Plants, being destitute of a heart, were consequently rejected from the law of centrifugal development, vegetable organogeny was separated from that of the animal kingdom, and a distinction was formed of so complete a nature, that its traces are not yet effaced. In after times the rapid progress of zoology bringing to light a multitude of animals devoid of a heart, these beings, which are classed under the name zoophytes, were reputed to be developed without a known cause. The centrifugal law was thus limited to vertebrated animals, or to those of the invertebrata provided with a heart. It thus ceased to be a general law, and in fact lost all application, since, in their primitive state, the embryos of the vertebrata are Zoophytes.

This insufficiency of the theory of pre existences and of the centrifugal law, led towards epigenesis two celebrated contemporaries of Haller, Needham and Wolf. The first attacked the hypothesis of pre-existences; the second the theory of cardiac or centrifugal development; and both of these suppositions would from that time have disappeared from science, had not these two anatomists combined with their sound reasoning on facts, those occult principles of development which led them astray. After exposing the fallacy of the preformation of germs, Needham made public his beautiful experiments upon the formation of the infusoria. He traced the development of the *monades*, of the *vibriona*, and of the *vorticella* in various vegetable infusions, and to avoid the objection that these germs floating in space might fall into the infusions, and be there developed, he repeated his experiments in closed vessels, without communication with the air, and in infusions from which all air had been expelled by strong ebullition. The results were the same in both experiments; the infusoria shewed themselves in the last as in the first. Now, do we not here behold, asks Needham, the image of the primitive creation of organized beings? Does not this present us an explanation of the mystery of generation? Without being acquainted with the ideas of Harvey upon the transformation of beings, he observed that, among the infusoria, some were arrested at a primary development, others at a secondary degree, while some, again, reached a ternary stage—so that their animality seemed to become more perfect at each development. From these experiments, Needham concluded, first, that animals are developed by epigenesis, and that that which we denominate a germ, far from representing on a minute scale the perfect animal, does not even contain its first outline; secondly, that there is a complete progression in developments, the organ in the primitive state of animality imitating a species of crystallization; thirdly, that animal and vegetable substances, considered in their original state, are identical in nature; so that, he adds, under the influence of certain conditions, animals become vegetables, and vegetables animals.

What a pity that such elevated notions should have been disfigured by suppositions the most unintelligible! According to Needham, the whole progress of development depends on an all-powerful *expansive force*, and on a power of *resistance* destined to counter-balance the effects of the expansive force; and it is by a continuous and alternate balancing of these two forces, that animal and vegetable formations are guided. Such were the unintelligible notions of Needham. These ideas have lately been revived by M. Oken, with this difference—that he substitutes *electro-magnetic attraction* and *repulsion*, in the place of the expansive and repulsive forces. These obscure notions, in like manner, pervade the otherwise grand researches of Wolf. Nowhere do we find a more powerful advocate of epigenesis than this illustrious anatomist; no one would have contributed, more than him, to place it on its true bases, had he confined himself to the strict interpretation of facts; but, after demonstrating the insufficiency of the *powers of expansion and of resistance*, as advocated by Needham, he, in his turn, imagined an *essential force* and a *solidescence*, which appear to be but a copy of the former. The confusion of the Wolfian theory of generation is evidently owing to the constant admixture of facts with principles not depending, or even totally disagreeing, one with another. But on analyzing these facts, we find that the development of vegetables takes place by a successive interposition of vesicles, which become deposited in the interstices of what Wolf denominates the cellular tissue, and that the formation of new layers is the result of this vesicular addition. Passing from vegetables to animals, we see that the primitive state of animality is constituted by globules; so that on tracing, for instance, the umbilical region of the chicken, we at first find but small globular bodies, which, uniting together, form lines, and then red points, which Wolf denominates *iles sanguines*; lastly, these points become covered with vessels before the appearance of the heart. Continuing his researches with respect to the formation of this latter organ, Wolf ascertained, on the one hand, the lateness of its appearance; and on the other hand, that when it does appear it seems to be quite immoveable. When, shortly afterwards, its movements commence, they are at first so feeble that the globule of blood oscillates, as if under the action of a peristaltic movement.—To sustain the now tottering theory of centrifugal development, Haller conceived that the parts previously existed, although invisible, and that the heart acted powerfully, although its presence could not be ascertained.

Thus did Wolf overthrow the theory of the centrifugal action of the heart, while Needham had, in like manner, disproved that of the pre-existence of germs. There still remained the spontaneous or successive development of parts, whereby epigenesis was equally distinguished from the system of pre-formations. Wolf rendered to science this new service; he shewed that the parts arise one after another, and even that they proceed one from another by way of secretion; he made especially this profound observation, already indicated by Needham, viz. that primitively all parts of the animal are fluid, and, as it were, inorganic, and that afterwards the vessels become developed within them by an action peculiar and in some measure inherent to their tissue. Haller, however, refused to admit these conclusions. Steadfastly following up the researches of Malpighi, he had been compelled to abandon the original notions of Bonnet. He had become convinced of the fallacy of attributing development to a simple increase. Struck with the observations of Needham and of Wolf, and seeing under the microscope, sometimes even with the naked eye, the organs change in form and position while passing from one state to another, he expressed these metamorphoses by the name of *evolutions*. The theory of organic evolutions is a formal protestation against that of pre-existences; for, according to the former, the embryo is no longer an exact miniature of the

perfect animal; it passes through states different to its original one: in a word, it changes. Still there is a difference between this and epigenesis. In fact, as his observations were not commenced until the first formations were not accomplished, Haller was enabled to reconcile with the theory of evolutions his favourite idea of centrifugal development by the creative action of the heart; for, as I have just said, in the theory of evolutions, our researches are only commenced when the first formations are accomplished, we have merely to follow organs already formed through the course of their various transformations. In that of epigenesis, on the contraray., our views are more extended; our object is to unveil even the formation of organs. The domain of the one commences where the other finishes; epigenesis is accomplished when evolution begins.

PERISCOPE OF THE WEEK.

Being Extracts and Condensations from the Foreign and Home Medical Journals.

General Ill Health. The disordered state of health, for treating which Mr. Abernethy gained such a reputation, is, says Dr. C. J. B. Williams, one of the commonest ailments we have to prescribe for: some call it, with Abernethy, "all stomach;" others, "liver;" others, "disordered constitution;" others, "indigestion;"—but however differently they may name it, few refuse to treat it, as Abernethy did, by regulated diet, blue pill, and mild saline aperient, repeatedly administered. Now the pathologist analyses the symptoms of such a state, and in the white or yellowish-furred tongue, morbid eructations, tender epigastrium, sometimes full right hypochondrium, with extended dulness on percussion, the discoloured fæces, the high-coloured and turbid urine, he finds proof of congestion and disturbed secretion of the liver and upper part of the alimentary canal; and he recognises in the remedies employed means which, by increasing the secretions, relieve the congestion; and if these fail, he can suggest other measures which he knows to be efficacious in removing congestion and restoring the natural secretions.

Absorption of Stomach.—Mr. Heron, of Lucan, mentions a sea-gull, accustomed to shew most voracious appetite, which, after being fed for a week on bullock's liver, declined eating or drinking, and died on the twenty-seventh day after being confined to the liver. On opening the bird, there were found neither stomach nor intestines; but in their place a light tissue of cellular membrane, with a little glairy yellowish fluid We are offered no explanation of this extraordinary result, except the incidentally mentioned fact, that the bird would swallow rats and mice whole, &c.

Encysted Abscess of the Brain.—Dr Browne, of Newbury, favours us with a singular case. The patient was a young female. The symptoms during life were, scrofulous aspect, pain over the *frontal* region, intense vomiting, of a peculiarly colored fluid: pulse seldom above 90, with heat of skin. After many days in this state, during which, the doctor considered her to have gone through the stages of common gastric fever, the pain in the head changed to the occiput, her stomach ceased to retain food when she reposed on her left side, hectic set up, followed by purulent expectoration, and death at the end of a seventy days illness. Though there was no delirium during life, convulsions, nor paralysis, nor ear ache, the *post-mortem* examination showed an encysted abscess as large as a walnut, filled with pus of a scrofulous appearance, in the left lobe of the *cerebellum*. The lungs were full of Tubercles.

Operations in the Parisian Hospitals.—M. Malgaigne, inquiring which are the most serious amputations—those performed on account of disease, which he calls *pathological*, or on account of injuries, which he terms *traumatic*, finds that of 789 amputations there had been 524 pathological, and 193 deaths, that is to say, 38 in 100; and 265 traumatic, with 130 deaths, or 19 in 100. He then divides them into greater and less amputations, the mortality in the former being 48 in 100 of the pathological, and 64 in 100 of the traumatic; in the latter 12 in 100 of the pathological, and 15 in 100 of the traumatic.—M. Malgaigne has only been able to obtain the documents of 26 amputations in the thigh; of these 16 were primary and 10 secondary: of the former 12 died, of the latter 6; and 43 amputatioos in the leg, of which 33 were immediate and 22 died, 10 were secondary with 7 deaths: but from these few cases M. Malgaigne would draw no conclusions. —With regard to sex, the results are: great pathological amputations; men 280, deaths 138; women 98, deaths 44. Smaller amputations; men 106, deaths 9; women 40, deaths 2. Great traumatic amputations; men 165, deaths 107; women 17, deaths 10. Small traumatic amputations; men 73, deaths 13; women 10, deaths 0. On the whole women recover better from amputations than men.—Age exercises a remarkable influence on the mortality. In great pathological amputations from 2 to 5 years, 4—2 deaths; from 5 to 15, 57—15 deaths; from 15 to 20, 66—28 deaths; from 25 to 35, 128—63 deaths; from 35 to 50, 72—40 deaths; from 50 to 65, 40—29 deaths; from 65 to 80, 11—5 deaths. In small pathological amputations from 5 to 15 years, 16—0 death; from 15 to 20, 27—1 death; from 20 to 35, 19—3 deaths; from 35 to 50, 33—5 deaths; from 50 to 65, 17—1 death; from 65 to 80, 4—1 death. In great traumatic amputations from 2 years to 5, 1—1 death; from 5 to 15, 9—7 deaths; from 15 to 20, 15—8 deaths; from 20 to 35, 65—39 deaths; from 35 to 50, 54—36 deaths; from 50 to 65, 30—21 deaths; from 65 to 85, 8—5 deaths. Small traumatic amputations from 5 to 15, 5—0 death; from 15 to 20, 12—1 death; from 20 to 35, 30—0 death; from 35 to 50, 28—8 deaths; from 50 to 65, 11—3 deaths; from 65 to 85, 3—1 death.—With regard to different seasons, M. Malgaigne finds that of 394 cases, 26 amputations took place in January—11 deaths; in February 24—12 deaths; in March 37—20 deaths; in April 28—11 deaths; in May 49—27 deaths; in June 46—27 deaths; in July 27—9 deaths; in August 45—21 deaths; in September 31—18 deaths; in October 32—15 deaths; in November 20—11 deaths; in December 26—9 deaths. So that in the four winter months, usually considered the most unfavourable, the mortality did not average one-half, whereas in the months usually preferred, it exceeded, that limit. The autumn is the most unfavourable, next to it the spring; and the result is the same whatever be the nature of the amputation. Nevertheless, winter appears as fatal to young subjects as it is propitious to the more advanced. M. Malgaigne next considers the relative mortality in the different Parisian hospitals, placing the Hotel Dieu sixth, and La Charite second in rank of success. In the most fortunate hospitals for pathological amputations, 1 death occurred in 5; and the least fortunate 9 in 10. In the most fortunate for traumatic amputations 3 deaths occurred in 10; in the least fortunate all the patients, who had been operated on died. M. Malgaigne does not pretend to explain this difference, but says it does not depend on the operator, as he does not carry his success from one hospital to another. All surgeons have considered a gun shot wound of the middle of the thigh to imperiously demand amputation; but M. Malgaigne considers this operation so dangerous, that he would prefer to leave the patient to the efforts of nature.

Genito-Urinary Organs.—Civiale conducts his *post-mortem* examination of these as follows. Incisions on each side of the body are carried from the external margins of the abdominal ring, so as to meet each other at the posterior portion of the anus, and the pubes and ischium are divided in the same direction. The kidneys are detached without dividing the ureters, and, having made an incision through the intestine at the sacrum, the contents of the pelvis are easily removed. Having placed the parts upon a table, the portion of the pubes and ischium which have been sawn through are removed, so as to expose the anterior part of the bladder, the upper surface of the prostate, and the deep portion of the urethra. A catheter is introduced, and, having punctured the bladder at its fundus, an incision is extended through its body and neck, and the membranous portion of the urethra, to the root of the corpus cavernosum. The lateral and lower parts of the urethra are left undivided, for it is here that the chief alterations are found, care being always taken at once to examine the orifices of the seminal canals. In many of the examinations which Civiale has made of persons who have died after retention, or other affection of the urinary organs, he has found great dilatation of these orifices, and large quantities of pus have issued upon pressure of the vesiculæ seminales. The changes in the vesicular are those usually found as the result of inflammation, leading to disorganisation; it terminates sometimes by suppuration, but usually by induration, or even ossification.

A Sheep's Tooth in a Child's Socket.—In 1841, Mr. Twiss, of Kerry, extracted a broken front tooth from a young lady, aged twelve years, and put in its place the front tooth of a yearling sheep, reeking from the jaw, having shortened its root a quarter of an inch. After the first week, the tooth at first being much too small for the space, it became more and more firm, and has enlarged, but not so much as it would have done in its pristine state; a circumstance observed in transplanted trees. Mr. Twiss selected the sheep from the extreme cleanliness of that animal, and the beauty and aptitude of the teeth, at two or three years old, when about the size of adult human teeth, and more likely to grow when transplanted. The root may be shortened or pared to fit and keep in *situ* by waxed silk ligatures.—

Employment of Belladonna in Phthysis.—Dr. Delhaye has derived much advantage in practice, from the employment of belladonna in the early stages of pulmonary tubercular phthsis, and against those prolonged nervous coughs which are the precursors of consumption. He administers the powdered root of this plant in fractional doses of from 25 to 50 millegrammes, in the course of twenty-four hours. In the case of irritability of the stomach, he prefers the extract or tincture of belladonna: the first of these two substances is prescribed in the same dose as the powder; the second, in doses of 20 to 30 drops. According to Dr. Delhaye, this tincture is also one of the best palliatives to which we can have recourse, to moderate the colliquative diarrhœa which so often cuts short the life of phthisical subjects. He considers it indispensable to the success of this treatment, that it should be adopted only when the stomach is healthy, and, according to him, gastro-enteritis is a formal contra-indication to its employment, the existence of which is frequently the first cause of the fatal termination to chronic diseases of the chest.

CLINICAL LECTURE DELIVERED BY MR. GUTHRIE, AT THE WESTMINSTER HOSPITAL, SATURDAY, OCT. 15TH.

GENTLEMEN,—I desired last Saturday that notice might be posted up in the hall, of my intention to give an introductory this day to my lectures, having refused to permit my name to be placed in the list of clinical lectures for this season, because I do not choose to promise that which I may not perform. I read in the *Lancet*, early in the present year, some incidental observations on this subject, from some one purporting to be a student: my mouth was immediately closed, not one word have you heard from me since. I have, however, now reason to believe that the gentleman who wrote these remarks, is not a student, and I do not think it right to punish the innocent for the guilty. I shall, therefore, notice some of these excellent cases, and bring the individual subjects of them before you,' which, during the first six months of this year, brought me almost without one exception every day to the hospital; and I shall be happy to think that even one half of you paid them only half the attention they received from me. It appears to me that some gentlemen wish to run down this hospital, both as relates to the relief the poor receive, and the instruction which students may obtain at it, by inveighing strongly against the management which does, and does not take place within its walls. I regret very much that many of the assertions of mismanagement, are, in all probability true as relates to the medical arrangements, many of which, are not in my opinion fitting for a public hospital in London. They are, however, all of them good, and well adapted for a parish infirmary; but, as long as it may be thought right to continue them here, the hospital must remain in a depreciated state, both as a place of refuge for the sick poor, and as a school of instruction.

When things become so bad that any change must be for the better, we may hope for improvement, and I care not how soon this takes place, for I confess, I shall look forward with the hope that this hospital will then rise from its remains, and assume that character, and obtain that reputation, it never can have under existing circumstances. I have done my endeavour to remove the abuses and grievances of which I am sensible; but I abhor all disputes and squabbling, more particularly when they become personal, and I have no wish to contend with gentlemen whom I personally respect, although I believe them to be in error; and even if I thought right to do so, I have not the time to spare which the forms of the hospital require.

With respect to you as students, I have not recommended one to come here, I have not invited you in any way, you have come because it suited your own views, and being here, I am at all times happy to give you every information in my power. My days of attendance are Tuesdays and Saturdays, according to the rules of the hospital. You will see it painted up in the hall that I also attend on Thursdays, believing that every physician and surgeon should see his particular case three days a week, and when I have any one in danger I visit them every day. You need never expect me before a quarter past one, and never wait for me after a quarter past two, before which time the assistant surgeon will go round with you, if I should be absent, and whenever he does the duty of one of the surgeons, he ought to receive a regulated proportion of the money which the seniors derive from the fees you pay for permission to attend.

I am never so contented as when you make yourselves constantly known to me, by obeying my injunction; so frequently repeated, of walking up to me, and repeating your names in my face; I do not desire one word more. When you wish anything from me, you have only to ask it; when you desire to have a clinical lecture on any subject, you have only to shew that you have yourselves attended to it, by presenting your own notes of the case, or cases, on which you wish to have my opinion, and your request will always be granted. You have only to conduct yourselves with order, regularity, and with strict attention to what I say to you, as there is nothing I can do, that I will not do to serve you; but as to obtaining anything from me by any other line of conduct, it is not to be done. I have never perceived the slightest mark of personal disrespect to myself on any occasion, and I believe it is the last thing any one of you would think of offering, and as to what idle persons may write in your name, we will not in future give it any consideration. I shall judge of you, by what you say and do here, and I will think the better of any young man who comes up to me boldly, but respectfully, to state his wishes or his grievances, even if the complaint should be against myself. With respect to the office I hold here, I value it very little as relates to money. There are two or three of the influential governors, who know it is at their service whenever they please to ask it, and, in fact, I only keep it because I hope the day is not very distant when I may be able to make my resignation more useful to the profession and to the public than it would be at the present time. I think it exceedingly unfair to the younger men, who are hanging on or about every hospital, that they should have no hope of the opportunity of distinguishing themselves, except by the death of perhaps their best friend.

The Governors of the Ophthalmic Hospital at once assented to my proposition that every surgeon should retire when sixty years old, and I shall retire when I attain that age, although, perhaps, that institution is indebted to my constant care and superintendence for its existence. I proposed to the Governors of this hospital that every physician and surgeon should retire at sixty-five years of age, and they were pleased to make it a law for all such persons who may in future be elected. They spared the present ones very much against my wishes, and have perpetuated an evil for some twenty, or perhaps thirty years, which I hope myself and my colleagues will have the virtue to remove. When I had the honor of being elected a member of the Council of the College of Surgeons, I found regulations existing which had been made many years, requiring an apprenticeship, or studentship, for six years, one only of which was required to be spent in studying surgery in a London hospital, for which year the same sum was paid, you pay now, the age for examination being 22. This I considered with others a great error, and we applied ourselves so steadily for its removal, that we have at last succeeded in reducing the time of study to four years, the age to 21. If the young candidate for the medical profession remains at school until he is seventeen, he will in all probability have profited considerably by its ordinary instruction, and have gained sufficient preliminary information to qualify him to pass through life without remark, if not with much credit, and I hope the forthcoming act of Parliament will enable us to secure such preliminary education, for I regret to say that among those students who entered the profession some years back, and are only now presenting themselves for examination under the Regulations of 1835, there are many who cannot spell very common words in their native language. If the first year of the professional education of a student were passed in the apothecary's shop of an hospital, or that of a practitioner visiting the sick wards occasionally, he would acquire a sufficient knowledge of the making up of medicine, and of the articles themselves, and something of other things that would smooth his path, and remove many difficulties which he would otherwise experience by going at once to lectures in an hospital. When we augmented the course of surgical study from one year to three, we took care you should pay no more than was expected from you thirty years ago, and the whole amount of fees for hospital attendance, including the practice of the physician, as well as of the surgeon, and all the lectures you are required to attend does not exceed at this hospital seventy pounds, and is very little, if anything, higher at any other. You could scarcely learn to black shoes in a fashionable manner—certainly not to make them—for less money. We did more—we considered that if we caused your friends to keep you at school until you were seventeen, instead of sending you into a shop to open the door, and perform other menial offices, at fourteen or fifteen, and thereby incur an additional expense in your education, we might with propriety save them the expense they would incur in your support the last year to 22, and we made the period of examination 21, instead of 22. We also removed the great grievance of which so much was made, of confining instruction to the London schools, and we enabled a student, who might live in a provincial town which had an hospital and school, competent for the purposes of instruction, to pursue his studies at home, and therefore at little or no expence. I always thought that we, who succeeded in effecting these things, had done the profession some service, and I have been surprised lately to see myself accused of doing exactly the reverse. It is true, I have not thought it necessary, to enter into explanations on these points. I have I fear, in fact, hid my light under a bushel. I have now ventured to state the fact, and I trust that those who had previously been misinformed, will not feel offended at my correcting these accidental misrepresentations; I will even beg of them to try me in future by a different rule, and whenever anything is done in which I may be supposed to have had a part, in which public justice, or the best interests of the public do not appear to be sufficiently consulted, and that private interests have been preferred, to believe that the transaction has not had my support. I am aware that in causing you to attend an hospital, and to study anatomy for three years, it may be said, that a horse may be brought to the water, but that he cannot be made to drink; which I do not dispute. I have, however, seen some thousands of horses taken to water, and have always seen them drink, unless they had lately drank before; and I am of opinion, that if a young man attends an hospital regularly, he is much more likely to learn than if he should not attend at all. The proof of such attendance is derived from the reports and certificates of the teachers, and if the regulations on these subjects had been duly complied with, that proof would have been complete. The surgeons and teachers of the large hospitals declined to comply, and the college gave way. I need not tell you the regret I felt on the occasion, and I may add, that there is no abuse so great in the profession as the manner in which gentlemen grant certificates; sometimes even of an attendance which has never taken place, and for persons not actually in the country, all I am willing to hope out of pure negligence; but the subject is too painful to comment upon, and my only consolation on this point is derived from the belief, that these irregularities will, in the course of the ensuing year, be effectually corrected.

With regard to the lectures you are ordered to attend, I am of opinion that every student should be a perpetual pupil to all; but I would not advise a regular attendance on more than one course of each, in order that the student may learn the history of the art and science he is afterwards to acquire a knowledge of by his own labours, under the observation and with the assistance of his teachers. On the study of anatomy I have much to say, but I have only time to point out to you, and to exhort you to avoid the error of learning anatomy in one place, and physic and surgery in another. Nothing can be more absurd than the peripatetic mode so frequently adopted, of walking from one end of this great town to the other to study anatomy, and back again to learn physic. They should both be taught at the same place, so that all the teachers may act together for the good of the student and the public, and where this is not done as it ought to be, I would recommend you not to attend.

I have heard it said that it is beneath the dignity of an hospital surgeon, or teacher, to ascertain whether his students are present or not, and that it is equally derogatory to the character of a student to have a watch set upon his attendance, to which I have always replied that the Regius Professors of Divinity, and others of equal rank, in the Universities of Oxford and Cambridge, do not think it unbecoming in them to ascertain that their students attend regularly, and that the hospital surgeons and teachers may do with great propriety what such men as these have done; and whilst the sons of the greatest men in this country

are regularly marked off every morning, as they go to-chapel in their respective colleges and the defaulters noted, medical students of the same age may and ought to submit to the same ordeal, which is purely for their advantage.

The inattention shown by many professors with respect to the attendance of their students renders another functionary necessary, who is called a grinder. As the time approaches for the final examination of the student at the College of Surgeons for the diploma, he becomes then sensible of the folly of his conduct in not attending to his studies; and he seeks a gentleman, who shall stuff as much information into him in a few weeks as may answer his momentary purpose. Thus crammed, as the term is, he fixes his day to go off, perfectly satisfied that he would forget all he had learned from his grinder in a month, if the grinding were not daily sustained. Under these circumstances, young men have frequently assured me they could describe a part or a disease they had not seen just as well as one they had. I have myself heard a student describe very well, the biceps flexor cubiti muscle, and not know it when shown to him. Anatomy is only to be learned by dissection; disease by attendance at the bed-side of the sick in an hospital. There is then to be acquired that confidence in your own knowledge which will enable you to manage and subdue a complaint without assistance from your teacher, and which confidence is only to be acquired by experience and observation—your whole life, in fact, must be one of continued study, and you will at last die having much to learn.

PRIVATE COURSE OF OPERATIVE SURGERY.

By J. NOTTINGHAM, Esq., Member of the Royal College of Surgeons of London.

LECTURE II.

GENTLEMEN,—The difficulty we have in tracing the precise limits of what is called operative surgery, declares at once the inconvenience, not to say the unscientific character, or absurdity of those divisions and subdivisions of the healing art, which frequently cause students to lose sight of the real affinities of its different branches, by attending to its arbitrary and apparent distinctions.

The expressions, *surgery and surgical pathology*, are, now-a days, often received as synonymous—while operative surgery, in which the hand of course is supposed to be engaged, does not generally include all those manual interferences, or operations which truly belong to the chirurgical part of therapeutics; for instance, the systematic works on this department of art frequently exclude all that relates to the application of bandages, or to the reduction of fractures and dislocations, a characteristic belonging more especially to the French treatises on this subject.

Some of the German writers have employed the name "Akieugie," for operative surgery; "'*Akis*, the needle, a point, &c., *Ergon*, work." while they have restricted the term Akologie to that which relates especially to surgical instruments.

The terms employed by the French are so much like our own, that we need not at present direct your attention to them; but here, and once for all, let us remark, that in this course of lectures, we intend to care less about words than about things, neither shall we feel ourselves bound to the repetition or adoption of such terms as akieugie, staphyloraphy, keratonyxis, scleroticonyxis, &c. &c., when any common English expression can be implied and at the same time convey an equally clear idea of what we mean; for no language can be regarded as pleasing which has not more or less the aspect of simplicity, and as we have a rich and beautiful tongue of our own, let us endeavour by the combination of its ordinary and intelligible elements, to make ourselves easily understood.

It is not perhaps a matter of very great importance which of the classifications of surgical operations we adopt, for scarcely any two surgical writers have agreed upon the peculiar excellence of any one method of treating this subject; we would recommend students to look at the systems adopted by Sabatier, Velpeau, and other French writers; and at those of Schreger, Zang, Grossheim, Blasius, and Biakowski, in Germany. Hitherto in England operative surgery has scarcely received that distinct consideration, which it has long had in the French schools. Hence the scarcity of systematic works on operative surgery which treat the subject in the manner of Velpeau, and others.

In some of the English works on descriptive and surgical anatomy, very valuable directions will be found, for the performance of many original operations, where a nice knowledge of the structure and relation of parts is required; this observation applies more especially to the operations for stone and hernia, and for the ligature of the arterial trunks, and the valuable writings and lectures of Key, Cooper, Lawrence, Liston, Quain, Harrison, and many others, will not be forgotten, while their value is duly appreciated.

INDICATIONS AND CONTRA-INDICATIONS.

If a patient suffer from a disease incapable of being relieved or cured by other means, and he be willing to allow of an attempt to cure it by surgical operation, more especially if he really desire that such operation should be performed without delay, and feel determined to rid himself of his complaint at any hazard; then would such operation seem to be indicated, provided that no accidental circumstance connected with age, or with bodily or mental condition present itself as a contra-indication, and oppose its execution. Circumstances, however, of this nature are numerous, and are every day met with by the surgical practitioner. Amongst them may be numbered the following:—

1. Peculiarity of age, as under 6 months, or more than 70 years of age.

2. Extreme weakness.

3. Great and unaccountable fear of the operation; especially of cutting instruments, or the fact of the patient having suffered in an extreme degree from minor operations previously performed.

4. Extreme irritability, such as to cause a fear of convulsions, extraordinary pain, or high fever,

5. The removal of large portions of the body, especially when this occurs suddenly.

6. The presence of diseases, such as scrofula, the venereal disease, or gout in an active state.

7. The fact of the disease to be operated upon having occurred from an apparently trifling cause, or its being developed in a manner, the nature of which is not apparent, but associated with some internal or constitutional change.

8. When the disease to be operated on is not purely local, or appears on some part of the body distant from that where its cause might have been expected to take effect; or when a similar disease prevails in different and distant parts of the body.

9. The long continuance of some general disease, which has caused the local complaint we have to operate on.

10. It is not desirable to operate on a patient who has lately undergone a course of mercurial treatment.

Lastly. Without further multiplication of such cautions, this concise one may be of use, viz., that the surgeon before he commences his operation, should ask himself whether he be about to do as he would be done by, *i. e.* whether on his own person, he would desire the operation under similar circumstances?

We cannot attach too much importance to the value of these contra-indications, in a general way, although cases of exception now and then occur, where prudence dictates an operation, although some of them may be present. An instance occurred to me about fifteen months ago, where in spite of the first contra-indication, or that of extreme age, it was thought proper, after due consideration, to amputate the fore-arm of a man upwards of eighty, who suffered extremely from disease of the left metacarpus. Every precaution was taken to prevent the aged patient suffering from great loss of blood, and the fore-arm was quickly removed, a narrow catlin being first passed through it before, afterwards behind the bones, and an anterior and posterior flap thus made; the case did extremely well, perfect union of the flaps having taken place in about a week. This venerable man was formerly in the navy, and was at the taking of a richly-laden Spanish galleon, about half a century ago, and he occupied himself during our amputation, by talking of the great prize he had assisted to capture. I saw him this morning, when he said that for some months after the operation he found his health improved, and accounted for this by his having got rid of the diseased hand.

The effects of impressions produced by great fear of cutting instruments, are sometimes sufficient to cause great apprehension,—and I well remember, at this moment, the horror depicted on the countenance of a young man of about 27, a patient of Dupuytren in the Hotel Dieu, who on the 30th November 1832, was brought into the amphitheatre, to have a large fatty tumour removed from the back of his neck. After a few minutes he allowed the operation to be performed, in which there was no particular difficulty.

He died on the third or fourth day after the operation, a *post-mortem* examination of the body was made, but no organic change was found which could be regarded as the cause of the fatal termination, and Dupuytren attributed it entirely to the great impression made upon this poor man by the fear of the operation.

While some patients evince the greatest possible fear of the approach of a surgical operation, there are others, who with an uncalled for bravado, pretend to treat it as if they could bear the torture it may occasion without betraying any emotion.

Both classes of patients must be carefully dealt with; the former are to be encouraged, and made to understand, that the value of the operation consists in this, that it is the most certain means which can be devised of removing, or mitigating the inconveniences or pains from which they have hitherto suffered: and if they greatly exaggerate its dangers, we must endeavour to disabuse them on this point.

The latter class, or those who might be suspected of displaying an artificial, or what might be called a morbid courage, must also be cautioned; they must be convinced of the importance to be attached to the part which they are called upon to act, and which they seem to approach with so little reflection. Let them understand that affected courage, does not take the place of real courage, and that it is dangerous to repress the expression of suffering, as it is useless to exaggerate it or utter it without motive, and that by doing so we violate the dictates of nature, which seem to be that we should always give utterance to the sufferings which our organs undergo, and that freely and without constraint.

It has been remarked by surgeons of great

experience, and Velpeau has well observed on this subject, that operations performed upon patients, pretending to, or rather displaying, an unusual calm and resignation, very often turn out unfavourably, and that generally speaking such an apparent state of feeling is to be regarded as a bad omen.

Occasionally in public hospitals we meet with those who appear to have a notion that they must be operated upon, whether they approve of it or no.—and the poor who suffer from diseases which come within the surgeons department, not unfrequently make this the source of an objection to enter a public establishment. It is of some consequence that such errors should be corrected by gentle treatment and persuasion, for by adhering always to truth there is no doubt but we shall be successful *in* eradicating them.

ON THE EMPLOYMENT OF THE KNIFE.

The surgeon should choose, hold, and direct this instrument, so as to suit the particular operation he has to perform.

Perhaps the choice of the scalpel, knife, or bistoury, is scarcely made with that care which is desirable; that this instrument may be exactly suited to the incisions about to be made with it, the surgeon's set of knives should be complete, and contain a regularly advancing series of blades, from the delicate little instruments, found in cases for operations on the eye, to the longest catlin employed in amputation at the hip-joint. To have such a complete set of knives, is found very convenient in the practice of amputations, as corresponding limbs vary so much in size in different patients. If the set of knives be complete, the surgeon can scarcely fail to hit upon one well suited to his case, while it is exceedingly awkward to be obliged to amputate a limb, or remove a breast, with a knife too long or too short.

Before we proceed to speak of the manner of holding the bistoury, let us remark that it is not customary to treat especially of surgical instruments, in works, or lectures on operative surgery; nevertheless the student ought to familiarize himself, with the many varied and curious productions to which the name surgical instrument has been attached; such observation and study, if it may be called so, will have the effect of convincing the observer of the uselessness of a great many of them, and of shewing the advantages to be derived from the employment of those which are the least complicated.

"The simplicity of an operation is the measure of its perfection," was a remark of the celebrated Desault, and its truth is so obvious that surgeons have ever since been pleased to quote it. Some surgeons, and surgical writers, have had a peculiar fondness for numerous instruments, and complicated operations, which only tended to display a host of difficulties, of their own creating, which their own ingenuity could surmount. However, the day for these things has gone by; medicines, and surgical instruments, are fewer in number, many surgical books are shortened, operations are less complicated, but more complete and successful; indeed, the mystery and bombast of the early fathers of the art can now be dispensed with, for surgery is becoming a very common-sense sort of business, and young men need not serve an apprenticeship of seven years to learn how to keep secrets, as was common in days of yore.

MANNER OF HOLDING THE KNIFE.

In the teaching of dancing and fencing, we hear first of the positions of the feet and body, in operative surgery the positions of the knife are first introduced to our notice, and of these the principal are three; for the bistoury may be held like a table-knife, in the manner of a pen, or like the bow of a fiddle; these positions, however, are capable of certain modifications which we will now attend to.

FIRST POSITION.

Bistoury held as a Knife, edge downwards.

In this position the joint of the instrument is pressed between the middle finger and the thumb, the index finger is a little advanced on the right side of the blade, and the two remaining fingers support the haft against the hollow of the palm; in this manner the bistoury is securely held, and can be easily manœuvred in any direction.

SECOND POSITION.

Bistoury held as a Knife, edge upwards.

The edge of the instrument being directed upwards, its point is seized betwen the index finger and thumb, the haft now turned towards the palm is supported by the three remaining fingers.

THIRD POSITION.

Bistoury held as a pen; edge downwards, point forwards.

Here the thumb and two first fingers support and hold the instrument, while the two last fingers support the hand, by taking a point of rest on the neighbouring parts.

FOURTH POSITION.

Bistoury held as a pen, edge downwards, point backwards.

If when the bistoury is held in the third position, the wrist be bent, and the point of the instrument directed towards the operator, this, the fourth position will be given to it, the end of the middle finger, slightly changing position or moving from the right to the left side of the blade.

FIFTH POSITION.

Bistoury held as a pen, edge upwards.

The name of this position is sufficient to define it.

SIXTH POSITION.

Bistoury held like the bow of a fiddle.

Pulp of the fingers pressing one side of the instrument, the thumb opposing them on the other; the edge of the instrument in this position may be directed upwards, downwards, to the right or to the left.

By frequent handling and manœuvring the knife, particularly on the dead subject, we shall become well accustomed to the sensations as far as our own fingers are concerned, connected with these different positions of the bistoury, and shall be able adroitly to take advantage of them as circumstances may require.

The degree of force, or the amount of delicacy, or caution, with which the surgeon may find it requisite to proceed, will generally suggest to him at once the choice of that position best suited to his purpose.

The knife positions of the bistoury enable us to employ considerable force, the pen positions are favourable to more delicate touches of the instrument, while the fiddle bow position partakes somewhat of both. The bistoury should not open with a spring like a common pocket-knife, nor should it, as is very common, be fixed between the two halves of the haft, by a mere rivet like a razor, but in addition to this, should have some sort of catch, to snap and fix it firmly when it is once opened; made in this way the blade will not wabble about, when steadiness and firmness are requ'red, and the surgeon will not be put out of temper by the awkwardness of a badly contrived instrument.

THE SCISSORS.

Are handled by the surgeon as by everybody else—surgical scissors are straight, curved in their breadth, or curved in their length. The latter kind were never much used in this country until Dieffenbach's operation for squinting became fashionable amongst us, and some 40 or 50 new instruments were invented for doing a little operation for which even a penknife, or pair of common scissors out of a lady's work box might have sufficed. However both the operation and scissors are now much less fashionable than they were twelve months ago; but although the latter have no particular utility, the former is undoubtedly effectual,

Scissors are seldom required to be sharp at the point, they are generally better a little rounded, unless otherwise formed for some particular purpose.

The opinion which has prevailed that the incisions made by scissors partake of the nature of contused wounds, does not perhaps merit any particular attention; I have operated several times for hare lip within the last two years, both with the bistoury and scissors, and have had no occasion to find fault with the latter for any effect allied to contusion; whether the bistoury and scissors cut by pressing, sawing, or the union of both, or whether each has its peculiar mode of dividing the parts through which it passes, we will not at present consider.

It has been recommended to dip cutting instruments in oil before they are used—this does not appear to me to be a matter of any very great importance, but I have always found them to act more agreeably when their temperature has been elevated by a previous dip into hot-water; we know that razors cut much better with this precaution, and that a warmed catheter passes along the urethra more easily than a cold one.

CLASSIFICATION.

Surgical operations may be conveniently divided into

ELEMENTARY, GENERAL, AND SPECIAL;

At any rate no other division of the subject occurs to me at present, better calculated to serve our purpose by facilitating our studies. In the first set or elementary operations, are included the considerations relative to the division and re-union of parts, the doctrine of incisions and suture, to which we shall proceed in the next lecture.

All that relates to the handling of the amputating knife and the saw, will be noticed in our introduction to the subject of amputation.

Before we close the present lecture, Gentlemen, I will introduce to your notice, the subject of operations, which by patients we are from time to time requested to perform, even when we may be of opinion that some contra-indication is in the way.

Such operations, when they are performed, are called by our polished neighbours the French "*Operations de complaisance.*" The best surgical writers however, do not recommend them, and it is easy to understand the necessity of abstaining from the running of any risk, where there is no probability of obtaining any comparatively good result; nevertheless there are cases of this kind, which present certain difficulties where it is not so easy to decide as might at first be supposed, as to whether the surgeon should yield to the importunity of the patient, or steer a decided course of opposition to his wishes. An operation would seem to me to be sometimes warrantable, although its issue be exceedingly doubtful, if the patient have a great desire that it should be done.

Certain cases of removal of malignant tumours might here be adduced by way of illustration. Cancer of the breast for instance, the removal of which by surgical operation is not now regarded in so favourable a light as it was twenty years ago. A case of this kind came under my notice last week, where a female, aged 45, a widow, who had borne children, called upon me not so much to consult me re-

specting the nature of a cancerous tumour of the left breast, as to request the immediate removal of the part by the knife. The nature of the case having been previously explained to her by other practitioners, and the operation, as the only possible means of cure, having been mentioned.

The tumour had already attained a considerable size, the nipple was retracted, or rather completely inverted, but there was no remarkable adhesion to the parts beneath, for the tumour was perfectly moveable in every direction and felt as if imbedded in a large mass of fat; the breasts in this patient being of unusually great size. From the feel and appearance of this cancerous growth, one would have supposed its development had occupied twelve months at the least; yet the patient's history declared that she knew nothing of it until between two and three months ago, when at its upper part the integument inflamed and ulcerated, adding that there had been no pain in the part before this period, and scarcely any since.

Her general health is excellent, and the aspect of the countenance healthy, with none of that sallowness or peculiarity of appearance so frequently associated with the existence of malignant disease.

The general health being good, the general aspect favourable, the tumour of the breast not adherent, the axillary glands having undergone no change that could be appreciated, and the patient wishing to have the diseased part "taken out as soon as possible," her request was complied with and the breast removed.

Here we may be allowed time for two or three remarks which will seem more or less out of place.

I have several times met with cases of schirrous tumours in the breast of women who had never borne children, and have some reason to think that cancerous degeneration of the mammary gland is more common where this structure has not performed the function for which it was destined at the ordinary period of life. In the case just now related, the affected breast had not been employed in suckling the children previously borne from want of development of the nipple, the opposite breast doing the office of both. Perhaps by the careful collection of a good series of facts of this nature we might, from correct statistical reports, ascertain whether or no any importance is due to these considerations, not only as they affect schirrous tumours of the breast, but in their application to similar diseases in the os and cervix uteri.

In the instance above noticed it might be said that the circumstance of perhaps an active secretion of milk without the ordinary efforts being made by the child for the depletion of its reservoir, was that which told against the future welfare of the part, suggesting the thought that want of exercition as well as secretion, may now and then interfere with the future safety of the mammary gland.

EXTRACTS FROM FOREIGN JOURNALS.

(For the 'Medical Times.')

FRENCH.—*Rupture of the Perineum throughout its whole extent; Communication of the Vagina with the Rectum; Successful Treatment by Suture.* By M. Roux.

Case.—Delalande, 22 years of age, of a good constitution, presenting a natural conformation of the pelvis and parts of generation, was put to bed for the first time. She experienced unsettled pains for the first 24 hours, the fœtus being in a good position, and the labour not much advancing, when the medical attendant applied the forceps. This unseasonable application caused great pain; the child was withdrawn, but at the moment of extraction the perineum was ruptured. The infant was well-developed; it weighed 18 pounds; the bones of the cranium were fractured by the forceps, and it died five minutes after birth. The lochia came away readily; the perineum was considerably inflamed; the bowels were not moved for seven or eight days, but for three months afterwards she was almost constantly affected with diarrhœa; the stools sometimes escaped involuntarily, and she became greatly weakened by the purging. The bowels were only slightly constipated by means of rice and coffee. She entered the Hotel Dieu on the 7th of August, three months after her accouchement.

Operation.—The day previous to the operation, we administered two lavements. Two portions of the skin were removed, so as to refresh the sides of the fissure, which had become cicatrized, and a similar process performed for the anterior surface of the recto-vaginal partition; three ligatures were applied by means of strong curved needles; the middle thread, finer than the other two, passed through the substance of the partition, so as to be brought forwards and fixed against the edges of the wound. After the application of the threads, and the approximation of the lips of the wound, a superficial twisted suture was applied, to keep in immediate contact the everted edges of the opening. A female catheter was introduced. The operation lasted 10 minutes. No bad symptom occurred, beyond a very copious muco-purulent discharge from the vagina. The operation was performed on the 11th, and the threads were removed on the 17th, after administering a dose of castor-oil the previous evening. She had, from the first, been unable to pass her water, so that it was necessary to use a catheter frequently, up to the 22d of August. When she left on the 30th, the cicatrix was firm and smooth; but there was a small recto-vaginal fistula behind; she was very weak. Three months afterwards, there was no trace of the rupture; the orifice of the vulva was greatly contracted. The small fistula had become completely obliterated, and all the tissues were firm and resistent.

Prolapsus of the Rectum of Six Years' Standing, occurring after a Natural Labour: Suture of the Lower Extremity of the Rectum: Incomplete Cicatrization. By the Same.

Case.—Janicot, 38 years of age, of a delicate constitution; this women had not always laboured under this affection. At the age of 32, after a natural and favourable labour, she for the first time perceived a tumour which escaped from the anus after the motions, or prolonged walking; this tumour she was obliged to return, although sometimes exceedingly difficult; from time to time, slight hæmorrhage occurred. For six years this state continued, without her being confined to bed; she, however, became greatly reduced, and was often troubled with diarrhœa. On the 8th of July, she entered the Hotel Dieu. Her appetite was still good. The tumour of the rectum was as large as two fists. This tumour, formed by the distended mucous membrane, was red and smooth; when pushed up within the anus, the perineum appeared flabby, the rectum relaxed, and the cavity above the sphincter of considerable size. By introducing the two fingers into the anus, the sphincter could be dilated, so as to shew the interior of the rectum.

Operation.—Two transverse incisions were made, each of the length of 3 *centimetres*, along the sides of the anus; from the outer extremity of these transverse incisions, two longitudinal incisions were carried, so as to converge towards the posterior part of the anus; in this manner two flaps were detached; the refreshed surfaces were drawn together by means of the twisted suture. A second superficial suture was afterwards applied, to keep the parts more perfectly in contact. Six hours after the operation, the patient withdrew the first suture, so that the superficial one alone remained; no hæmorrhage had supervened. During the last seven days, she hadhad no stool; some castor-oil was given her; copious stools during the night; no prolapsus had since occurred. On the eighth day, the remaining threads were removed. The twentieth day,—diarrhœa occurred; she was obliged to make continual strainings; the prolapsus, however, has not reappeared. The operation has apparently succeeded; but a relapse may probably occur as the layers are but superficially cicatrized. Complete cicatrization would probably have occurred, and so a perfect cure have been established, had not the patient had the stupidity to remove the suture a few hours after the operation.

SCHOOL OF MEDICINE, PARK-STREET, DUBLIN.—The Winter Course will commence on the 1st of November.
Anatomy and Physiology—Hugh Carlile, M.D., T.C.D., John Denham, M.D.
Surgery—J. W. Causack, M.D., M.R.I.A.; John Houston, M.R.I.A.; C. Fleming, M.D., M.R.C.S.I.
Chemistry—John Aldridge, M.D.
Materia Medica—Richard Eades, M.B., T.C.D.
Midwifery—James Isdell, M.D.
Medical Jurisprudence—Henry Forde, M.B., T.C.D.
Diseases of Eye and Ear—Wm. R. Wilde, Esq., M.R.I.A.
Anatomical Demonstrations—John Denham, M.D.; John Hill, M.B., T.C.D.; R. M'Donnell, Esq. L.R.C.S.I.
Dissections,—Under the superintendence of the Lecturers on Anatomy and the Demonstrators.
Secretary, JOHN HOUSTON, M.D., 31, York-street

TO CORRESPONDENTS.

The interesting case of Epidemic Erysipelas in an early number.

We have received a second startling communication from Mr. Macpherson Adams on his Mesmeric Experiments in Paris, which we shall publish in our next number. It is right that we should add that we have the authority of a gentleman connected with our office, and on whose honour and judgment we place implicit reliance for saying, that no man has been less open in his past character to the charge of credulity, and none has ever shewn a higher respect or zeal for truth for its own sake, than the Mr. Adams to whom we are indebted for these singularly interesting communications.

Potash Water.—*A Subscriber thus writes to us on the subject of the recent inquest :—*

"Sir,—Methinks, Mr. Editor, there has been a little too much of *self* manifested by the surgeon throughout this affair—too much of an utter recklessness of whom he drew into the halter, so as he himself kept his neck from the noose. I should imagine it would be difficult to find a druggist in the kingdom who would not have acted precisely as did the one in the present case. The 'Liq. Potassæ' is very generally enquired for and spoken of as 'Potash Water.' In the Ph. Ed. it is called 'Aqua Potassæ,' and under these circumstances is not a man justified in sending out Liq. Potassæ for Potash Water. To suppose a person required the aerated, the '*real potash water as purchased at the shop of Savory and Moore, the well-known chemists of Bond Street, which completely resembles in colour and appearance a bottle of soda-water*,' would be an illegitimate stretch of the imaginative faculties. To label, indeed, such an article as Liquor Potassæ 'poison,' would evince an old womanish sort of caution, and by the prescriber would probably be taken as a marked affront, if he had intended that article. As well might the druggist label 'poison' the tinc. hyas.—tinc. colch—tinc. ferri sesquichlor.—tinc. canth.—æther.—and such like,because in large quanties they might destroy life."

We are not of our Correspondent's opinion on the propriety of the Druggist's conduct. On the contrary, we believe that in a case of doubt, he acted in a mode which would have been perfectly unjustifiable in a state of certitude. The messenger's account was . ost unsatisfactory, and, if perfectly satisfactory, no such preparation should have left his shop without carrying with it an indication of its dangerous qualities. The Surgeon's procedure was slovenly, and culpable to a most lamentable extreme, but if the Druggist had discharged his functions with due caution, the calamity which now presses on the character and peace of both would have been spared. These remarks must be our notice to several other correspondents who have written to us on this subject.

Several Communications have been sent to us which are under consideration.

Declined.—*Mr. T. F.—An Antiquary—The Ghost of the Lancet—Minos—A Pupil of Bartholomews' Echo—A Well Wisher—A Subscriber, (Edinburgh) —A Constant Reader (Edinburgh)—A Constant Reader (Beverley.) Some of the communications, however, will be turned to account.*

We have received accounts announcing meetings of Students' Discussion Societies in several of the Hospitals. Our space has been so much encroached upon by what even our friends, the students, will probably consider more important matter, that we can only do ourselves the pleasure of expressing the high gratification with which we hear of their very praiseworthy and self-rewarding efforts. We are glad to hear that the lecturers at Westminster Hospital, the King's College, and Charing Cross, are giving these best of schools a warm support.

A Practitioner before 1815.—*The College of Surgeons now admits (as we sometime since suggested it should do) respectable practitioners to examination without certificates, &c. The fee for the diploma, however is not reduced.*

We are asked "why the worthy Council of the College in Lincoln's Inn, have omitted in their list *the dates of their own diplomas, having published those of all other members?" We are not perfectly in the secret; but know that the omission was the result of careful deliberation. Some say that the thing originated in a piece of delicacy—in the fact that the rule was, that the place of the last new member of Council on the list marked a point, up to which the older, and yet excluded surgeons, had no chance of entry—for having once been passed by, their claims could never be reconsidered. Others say that the Memento was omitted on the principle which makes (we do not say* other) *ladies of a certain age, proscribe every fact which marks their whereabouts in the scale of time. For ourselves we attribute the important distinction to some sublimity of policy, whose heights and depths can only be fathomed by our* taciturn *friend, Mr. Babington.*

Dr. Wake.—*The double supply must originate, we should think, in a second order to another quarter. The rest will be carefully attended to.*

ERRATA.

In Dr. Hunter's Lecture in our last number, at page 37, col. 1, for *ulcerated* cells, read *nucleated* cells; and in Professor Owen's Lecture, page 35, col. 2, for *Gall* read *Gall*.

THE MEDICAL TIMES.

SATURDAY, OCTOBER 22, 1842.

They manage these things better in France.—STERNE.

OUR readers will remember that we last week spoke of the *amabilis insania* of the Drug Solons of Cockayne—the enterprising gentry, who, though smitten with the tongues of heaven knows how many bad and conflicting interests, are thinking of piercing the skies with a Pharmaceutic Babel. On reviewing the terms we then used, we are struck with their lacteal mildness, and at the wide chasm which gapes between them and the mighty presumption they aspire to depict. In the whole range of legislation we know not where to find a question, which, threatening to affect so extensively large social and class arrangements, involves higher matters of right, or expediency, or brings under discussion, subjects of more complicated, or momentous interest, than the question which yet to be settled between the British druggists on the one hand, and the British Medical profession and the public on the other, has been coolly taken up for definitive arrangement by Mr. Jacob Bell, and some half dozen dispensing hands of his domestic acquaintance. Napoleon's highest feat—which will endear him to philosophers, when children shall have learned to speak of his military name with horror or contempt—his immortal code of laws,—this in its different parts presents no higher distinction wherewith to wreathe his massive brow, than the magic power with which he formed for his country an enlightened body of pharmaceutists, and guaranteed to her in perpetnity, with the least possible drawback, all the benefits which the very best governmental arrangements could extract from them. If our governors (shall we include our pharmaceutic committee-men?) have the aid of his splendid example, it must be remembered that they have also difficulties which he had not. England is no *tabula rasa*. Its habitudes and laws of centuries oppose a stout barrier to all legislation, which is at once novel and bold. In its complicated social state, the destruction of the *bad*—especially of a *bad* extensive and involved as that we are considering—is often a greater difficulty than the erection of the good. Yet here we must either have old habits and laws swept away by wholesale, or grapple with the harder duty of making our new arrangements destructive of the old evils, yet in symmetry with the old system. Enlightenment in the lawgiver, and fairness in the legislation, are not enough,—power and boldness must correspond. The best of changes in England must be evil for some one, and the man knows little of English history, who knows not how often the justice a well meaning lawgiver would do to posterity, is arrested by the hardships the act would inflict on contemporaries, or how often the boon demanded by fairness for the many, has been denied by the cruelty its concession would be to the few.

The regular induction of pharmacy into our country, and its establishment as a science with a competent body of cultivators—things that yet rank in the class of *desiderata et valde deflenda*—is a work of three aspects, each of dominant importance. The pharmaceutists, medical men, and the public, are each and all interested in every step taken ; and contending, as may appear their varying claims, or rather rights—we dare not say interests—the legislator, who undertaking the matter, shall fail completely to reconcile them, will have worked to little purpose. For our part—though without believing that the solution of this difficulty is *quite* so easy an affair as Messrs. Bell and Company evidently consider it—we venture to think that the simple, but comprehensive scheme we have often glanced at, and now more distinctly propound, if carried boldly and prudently into practice by a well meaning government, would, while doing justice to all parties, and no small service to science, relieve us for ever from this vexatious and harassing question.

Firstly.—We would ascertain the competency of every druggist in the Empire to perform the duties of his position. To this end we would at once have provisionary Courts of Examiners appointed. No man who should not satisfy them that he could discharge the functions of a druggist with safety to the public, should be allowed to practise pharmacy. The result of this would be obviously the retirement of hundreds of druggists ; a far less evil, however, than their continuance in practice. These useful secessions would cause no inadequacy of supply : our own unemployed, but tested brethren, would be too happy to fill the vacuum.

Secondly.—All druggists passing these

examinations satisfactorily should, without charge to them, have a diploma attesting their competency, and a license, allowing them to practise pharmacy. The process is for the public's good; and the public should pay for it.

Thirdly.—Provision should be made for securing the public, in the future, with a full supply of the most highly-educated pharmaceutists, that state-wisdom and power could produce. To this end, a good preliminary education should be demanded from every one commencing the study of pharmacy. A limited knowledge of Latin, if not of Greek, and a solid acquaintance with his own language, are of primary necessity; and, low as education undoubtedly is in England through its inaccessible expensiveness, these should yet be arbitrarily insisted on. Two years with a licensed druggist, though perhaps a matter of doubtful necessity, might not unreasonably be asked. Three further years should be spent at a government College of Pharmacy, which should at once be founded; and when this course is completed, an examination should be demanded always sufficient to protect the public—but varied in severity, proportionately, to the numerical wants of what would now be—a profession. We are far from wishing to limit freedom of education, especially, when competency is to be tested by a final examination; but the wretched position which English pharmacy now occupies, makes us see several utilities in the establishment by government, of four or five central normal schools, where the experience and knowledge of our few able professors might be turned to the most extensive and profitable account possible.

Fourthly.—We would adopt measures to confine pharmaceutists to their own profession. We would, by an enforced public inscription in their shops, exactly teach the public, the character of their knowledge and duties; we would have their licenses dependant on the honesty of the possessor's practice; we would enact small penalties, easily and speedily levied, for every open invasion of the doctor's domain, and provide *that* severe punishment (quickly inflicted), for serious ill consequences of malpractice, which would make it the *interest*, of even the unprincipled, not to incur the hazard. This, to the druggists, will appear severe; but it is no less essential to the due honour of their own study, than to the preservation of the just rights of the medical profession—and the safety and well being of society. Pharmacy with all its varied divisions, and exhaustless materials, will task singly the utmost efforts of its ablest and most devoted cultivators, and that government can scarcely lay claim to the merits of paternal economy, or sound policy, which, by its non-interference, encourages its subjects to those divided and distracting labours which makes them *useless* to one highly important profession, and noxious to another. If the claims of pharmacy—so disgracefully low in our otherwise distinguishingly scientific country—be too weak to influence our governors to put a stop to that dishonest intermeddling of druggists with a business to which they are no more akin than the thousand other classes of tradesmen, who aid in keeping the animal economy in a state of comfort or health, let us beg them to remember that the existence of one of the most useful classes of men in the country, our medical practictioners, is more emperilled by the continuance of so gross an abuse than is usually surmised. Our profession opens to the young generation no glittering honours—no very probable chances of large fortunes; it is comparatively costly of entrance: years of peculiar duties and hard and repulsive studies are necessary preliminaries: ceaseless confinement as to time and place—drudging attendances in all weathers, and all seasons of the day and night—limited remuneration—and endangered, and usually shortened, lives; these, the common fate of medical men, are the prospects which (with darker shadows every new day), stand before the youth who thinks of entering our profession.

Need we remind our governors that while the very men we want—men of respectability and cleverness—will be certainly kept out under such a system, we can have no very secure guarantee on the other hand, that a sufficient number of our body of even ordinary qualifications, can be permanently sustained to supply the wants of the public? We are not dependent on speculation in coming to this conclusion. The recent entries at our metropolitan and even provincial schools, speak trumpet-tongued of the diminution of medical candidates, and we venture to tell our Government, that if it does not take some efficient steps, we will not say for the encouragement, but the protection, of our profession—among which we consider, as of the very highest importance, the destruction of that alarmingly increased, and increasing evil—druggists' medical practice—a day may come which will present our present superabundance reversed, and show to us our country—it may be in a period of pestilence—deprived of that boon, which, like so many other blessings, is only properly prized and appreciated in its absence and in the hour of need—an enlightened, a learned, and a benevolent medical profession.

PREPARATION OF ERGOT OF RYE.

To Charles Clay, M.D., Manchester.

Sir,—It was with great pleasure that I read your observations on the ergot of rye, published in Medical Times for Sept. 3d, and in every respect do I agree with you as to the priority the decoction of ergot of rye claims over every other preparation of that drug; but there are to be met with many cases where the secale cornutum is especially indicated and where the delay in its administration occasioned by the necessity for its extemporaneous decoction, would be attended with dangerous and not unfrequently fatal results.

If you could point out any way in which this evil might be obviated, it would doubtless be read with great eagerness and attention by many others as well as your obedient servant,

J. Ridout.

Stratford, Essex. Oct. 10, 1842.

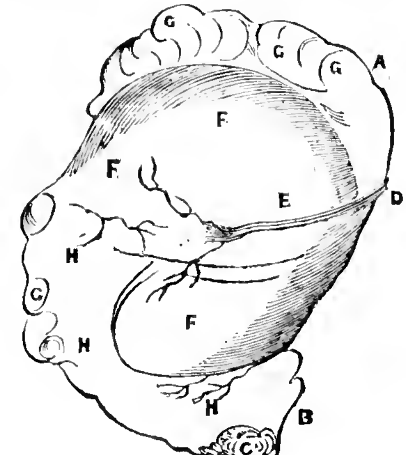
CASES OF PERITONEAL SECTION FOR THE EXTIRPATION OF DISEASED OVARIA BY THE LARGE INCISION FROM STERNUM TO PUDES, SUCCESSFULLY TREATED.

By CHARLES CLAY, Member of the Royal College of Physicians, London; of the College of Surgeons, Edinburgh, and Lecturer on Medical Jurisprudence, &c. Piccadilly, Manchester.

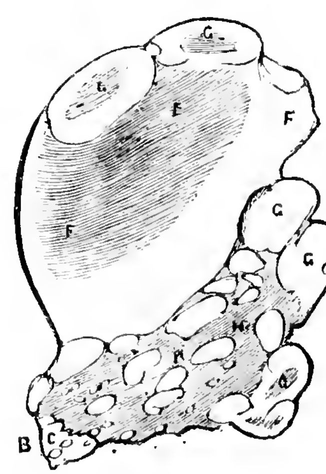
(Continued from page 45.)

DESCRIPTION OF THE TUMOUR.

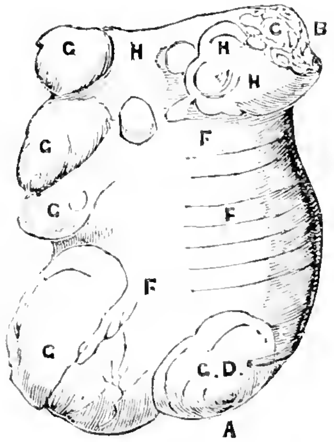
The tumour weighed 17 pounds 5 ounces, apothecaries' weight, and its largest circumference was three feet, eight inches, its shortest circumference two feet, inclined to be oval in its form, *fig.* 1. The part marked A was situ-



ated under the umbilicus, and formed the most prominent part of the abdomen. B was the pelvic mass, of which the part marked C was ulcerated. D. the pedicle, where it was cut. E the fallopian tube, broad ligament, &c., attached to the tumour. F F F the large sac capable of holding about six pints. G G G smaller sacs holding from half an ounce to half a pint each. H H H the solid part of the tumour composed of still smaller cells, filled some with pus, others with a brain-like substance, the interstices being fibrous and cartilaginous, in some parts so hard as to injure the edge of the scalpel. The contents of the large sac were a thick glutinous substance not unlike the albumen of an egg half boiled, but in no part did I observe the coffee-coloured liquid noticed by most writers; the fluid here found coagulated on the application of heat. *On the opposite surface* the smaller sacs, to the number of six or seven in the whole, were more distinct, as in *fig.* 2, marked by the same references as the last diagram.



A view of the tumour in section will show the more solid part of the tumour distinctly from the large sac, *fig.* 3.



Independent of the tumour and its contents, there were about six and a half pints of ascitic fluid in the abdominal cavity. When the inspection of the tumour took place, Drs. Radford, and Black were present. There are many circumstances connected with these particulars, I wish the reader to bear in mind, as they are of great importance in determining on the plan of operation; and by which, I shall endeavour to shew, that under the well known obscurity which exists in the symptoms of all ovarian tumours, the operation by large incision is safer, and better than any other plan.

SUMMARY OF THE FIRST TWENTY-FOUR HOURS AFTER THE OPERATION.

Temperature of the Apartment.—It will be observed that the room was kept as nearly as possible to one temperature; a circumstance of no small importance in the management of so critical and serious a case.

Pulse.—The circulation with those exceptions marked at the 8th and 19½ hour after the operation, was soft and easily compressible; at the two periods alluded to, it was a full, strong, and hard pulse, consequently bleeding was resorted to; at the 8th hour to ℥xiv, when sickness occurred, and again at the 19½ hour to ℥viij, when sickness came on. After the first bleeding the pulse fell to 84 and soft. After the second it rose to 100, but remained soft and feeble, both bleedings exhibited the buffy crust. The blood was taken quickly from a large orifice.

Skin.—After the first six hours had expired, (the skin was generally warm and moist during the six hours alluded to,) the face, hands, and feet, were particularly cold, and moist, like the asphixiated stage of cholera. At the two periods, when the pulse stood at 90, the skin was hot and dry.

OPERATION, 4 O'CLOCK P.M., SEPT. 12, 1842.	½ past 6—2½ hours after operation.	8 p.m.—4 hours after operation.	10 p.m.—6 hours after operation.	12 p.m.—8 hours after operation.	¼ to 4 a.m., Sept. 13th—11¾ hours after operation.	6 a.m.—14 hours after operation.	9 a.m.—17 hours after operation.	½ past 11 a.m.—19½ hours after operation.	1 p.m.—21 hours after operation.	¼ to 4 p.m.—21 hours after operation.
Room Temp.	70	70	70	68	70	68	68	70	68	70

Sleep	None	None	20 minutes	10 min. sound	80 min.	70 min.	20 minutes	None	20 minutes	120 minutes
GENERAL REMARKS.	Face and feet particularly cold—ordered stockings on the arms and legs—gave mur. morphine, gr. ss. in pill—gruel diet—toast water—panada—and softened German rusks.	Ordered the room windows opened—and a cup of tea—former diet.	She felt sleepy, and as the morphine had not produced any sleep gave her m. 30 tinct. hyoscyami—felt a little pain at the ligatures when coughing—diet continued.	As the pulse was 90 full and strong—bled from a large orifice to ℥xvi, when sickness came on—pulse after bleeding, 84, and soft—and a dew of perspiration covered the skin—diet continued.	The urine drawn by the catheter was of a pale sherry colour, natural in smell—diet continued.	Feels a little soreness in the line of the sutures—the blood drawn at 12 o'clock exhibited a buffy crust—when still, perfectly comfortable—diet continued.	Ordered enema, with ol: ricini—and to be repeated two or three times, if necessary—diet continued.	The enemas were not up to this time ejected, they were repeated—bled to ℥viij, when she felt sick—pulse after bleeding, 100, but soft and compressible—perspiration came out over the whole body.	Still no return of enemas—had vomited twice—the blood previously taken shewed a buffy crust—enemas with ol. terebinthinæ and ol: ricini ordered, and to be repeated two or three times—diet continued.	Still no return of enemas—urine natural colour and smell—flatus for the first time—ordered a continuance of enemas—patient expressed herself hungry—diet continued.

Tongue and Thirst. During the first twenty-four hours the tongue kept remarkably clean and moist, with the exceptions as above; when the pulse stood at 90, then the tongue was clean, but dry, accompanied with thirst. I may observe, however, that the thirst was never to any extent throughout the case.

Flatus.—It was truly astonishing how free the bowels were from flatus at the time of the operation, and even for some days after, but particularly during the above tabulated twenty-four hours, which I attribute to the peculiar evacuant power of the inspissated ox gall given before the operation to unload the intestines; the satisfactory effects of which I had very frequently proved, and recorded my experience of it in the MEDICAL TIMES.

Pain.—During the first six hours there was very severe pain in the loins and right iliac region, this was attributed to the stretching of the pedicle, and adhesions of the tumour during the operation, and to the ligatures left on the vessels and pedicle, a circumstance wholly impossible to avoid. After the first bleeding the pain left the parts; a slight recurrence of it came on a little before the second bleeding, after which it was wholly and effectually removed, and has not since returned. In testing the abdominal region for the purpose of discovering any tendency to inflammator

General Remarks.	Vomiting.	Sleep.	Motions.	Urine.	Cough.	Pain.	Flatus.	Thirst.	Tongue.	Surface of the body.	Pulse.	Temperature.	From 24 Hours after the Operation, to the Conclusion of the Fifth Day.
Enemas continued—Gave mur: morphine half a grain.	Three times.	60 min.	None.	None.	Little.	None.	None.	None.	Clean.	Warm and moist.	106 Soft.	70	½ past 7 o'clock p.m. 27½ hours after, Sept. 13.
The morphine not effective, gave her Tinct. Hyoscyam. 50 drops in tea—Clysters not yet returned	Twice.	15 min.	None.	None.	Little.	None.	None.	Trifling.	Clean.	Warm and moist.	90 Soft.	70	12 o'clock, night, 32 hours after.
Patient very cheerful—Vomiting not distressing—Some of the last clyster returned—Urine, natural in colour, and smell—Diet continued.	Thrice.	240 minutes.	Very little.	Drawn ℥vi.	Little.	None.	None.	More.	Dry.	Warm.	90 Fuller.	68	½ past 6 a.m., Sept. 14, 38½ hours after.
Belly slightly tympanitic—Flatus felt for the first time—No more clysters returned—Clysters repeated.	None.	60 minutes.	None.	None.	Little.	None.	Little.	Very little.	Moist, a little scurf.	Warm and moist.	105 Softer.	68	41½ hours after operation.
Still no return of the clysters—Urine natural—Flatus more troublesome—Diet and clysters continued.	Once.	80 minutes.	None.	Drawn ℥v.	Little.	None.	Little	Little.	Rather moist.	Warm and moist.	86 Soft.	70	46½ hours after operation.
Felt a sensation as if a motion would come.	Three times.	30 min.	None.	None.	None.	None.	Little.	Trifling.	Moist.	Warm and moist.	112 Soft.	70	49¼ hours after operation.
Still no motion from the bowels.	None.	90 min.	None.	None.	Little.	None.	Little.	None.	Clean.	Warm and moist.	90 Soft.	68	52 hours after operation.
Clysters were again given, and the abdominal region assisted by a six-tailed bandage—A large mass of clyster and fœcal matter returned.	Once.	100 minutes.	None.	None.	Little.	None.	Little.	Trifling.	Moist.	Warm and moist.	88 Soft.	71	55¼ hours after operation.
A tube introduced into the rectum, an enormous quantity of flatus was discharged—Takes her diet very well.	None.	195 minutes.	None.	Drawn to ℥xii.	Little.	None.	Considerable.	None.	Clean and moist.	Warm and moist.	86 Soft.	70	62 hours after operation.
Feels perfectly free from pain,—only tired of lying on her back, and very hungry.	None.	50 minutes.	None.	None.	Little.	None.	None.	None.	Little furred.	Warm and moist.	86 Soft.	70	65½ hours after operation; ¼ past 9 o'clock, a.m., 15th.
Diet continued.	None.	40 min.	None.	None.	Little.	None.	Very little.	None.	Moist and red tipped.	Warm and moist.	82 Soft.	71	70 hours after operation.
Diet continued.	None.	None.	None.	None.	Little.	None.	Very little	Little.	Furred	Warm and moist.	84 Soft.	70	73½ hours after operation.
Clysters ordered to be continued, with the assistance of the bandages—Fæcal matter brought away—Urine natural—Gave Tinct. Hyoscyam as before.	None	90 minutes.	None.	Drawn to ℥xii.	None.	None.	Very little.	None.	Cleaner and moist.	Warm and Moist.	76 Soft.	70	79 hours after operation.
Diet continued.	None.	135 minutes.	One, natural.	None.	Little.	None.	None.	Little.	Rather dry.	Rather dry.	80 Soft.	70	7 o'clock a.m., Sept. 16, 87 hours after.
Diet continued.	None.	None.	None.	None.	None.	None.	None.	None.	Moist.	Moist and warm.	84 Soft.	70	90 hours after.
Diet continued.	None.	45 min.	None.	None.	None.	None.	Very little.	None.	Clean and moist.	Warm and moist.	86 Soft.	70	96 hours after operation.
Diet continued.	None.	None.	None.	None.	None.	None.	None.	Very little.	Moist and furred.	Warm and moist.	100 Soft.	71	100 hours after operation.
Aphthæ appeared slightly in the mouth—Ordered a linctus, with Borax soda—Repeat enemas—Half-a-grain mur. morphine, and 50 m. Tinct. Hyos. at bed-time.	None.	None.	None.	Drawn to ℥vi.	None.	None.	Little.	None.	Cleaner.	Moist and warm.	86 Soft.	70	104 hours after operation.
Felt very well—Clysters not returned—Complains of hunger—Diet the same.	None.	4½ hours.	None.	None.	None.	None.	None.	None.	Clean and moist	Warm and moist.	80 Soft.	70	Sept. 17th., 7 o'clock a.m., 112 hours after.
Diet and drink as before.	None.	None.	None.	None.	None.	None.	None.	None.	Clean and moist.	Warm and moist.	84 Soft.	70	111½ hours after operation.
First time of passing water naturally—Dressed the wound—Found it healed, except helf-an-inch at the umbilicus, and half-an-inch where the ligature passed outward—Changed her bed and linen—Did not appear fatigued with the exertion.	None.	None.	Three, natural.	Naturally, ℥xvi.	None.	None.	None.	None.	Clean & moist.	Warm & moist	74 Soft.	70	122½ hours after operation.

action, both general pressure, with the hands spread, and particular pressure over various localities with the tips of the fingers, were resorted to, and this is to be considered when speaking of absence or presence of pain in the future statements of the case.

Light-headedness.—Not the slightest disposition to this tendency manifested itself (with the exception of about an hour before the first bleeding, after which it never occurred again.)

Cough.—It will be observed that occasionally a slight cough troubled her; this commenced about six hours after the operation. It appears from inquiries made, she was suffering from a little cold at the time of the operation, but about which she kept silent lest the confession might delay the time of performing it. Although it was but slight, and no bad effects arose from it, yet I must confess had I been aware of it, I should have postponed operating to a more favourable opportunity.

Shivering.—This never occurred but once, and that during the first two hours after operating, and then but slightly.

Hæmorrhage.—This much dreaded item never made its appearance, even in the slightest degree during the whole progress of cure.

Urine.—The bladder being effectually emptied at the time of the operation by natural means, there was no call for the catheter until near twelve hours after the operation, when six ounces were drawn off, of a pale sherry colour, and natural smell. The catheter was again introduced at the expiration of twenty-four hours, when eight ounces were drawn off, of a natural smell and colour..

Motions.—No evacuations from the intestines during the above twenty-four hours took place, although enemas were freely and frequently administered at the early part of the time with oatmeal gruel and olei ricini, and the latter part of the same time with the addition of the olei terebinthinæ. In this, there was nothing very remarkable, as the bowels had been so effectually emptied by the exhibition of twelve grains of the inspissated oxgall before the operation; a preparation in which I have the utmost confidence as an evacuant without creating the least excitement, and which in my opinion is far preferable to doses of drastic purgatives, as recommended by Mr. Lizars, preceding the operation.

Respiration.—This function was never in the least degree interfered with during the progress of the case, the breathing being always perfectly easy.

Coldness.—During the two hours this sensation was felt severely, the face, hands, and feet, had much the same character as asphixiated cholera; at the termination of the second hour it disappeared and never recurred again.

Sleep.—The portion of the twenty-four hours spent in sleep amounted to six hours and ten minutes, and this at ten different sleeps. As there are but seven mentioned in the table, I may observe that the third, fourth, and last items are two sleeps combined together.

Diet.—The diet was of the simplest possible description, every thing in the shape of stimuli carefully and rigidly avoided. Boiled bread, toast water, thin solution of gum arabic, arrow root, gruel made in water, and German rusks, softened in toast water, formed the only diet for the first five or six days; and from that time to the twelfth day only tea, coffee, and a little milk to the water, with which the arrow root was made, were the only things added to the former articles of diet.

Vomiting, I ought to have observed, occurred twice towards the conclusion of the first twenty-four hours; it appeared to arise from the taste of the olei terebinthinæ, which had risen to the mouth from the enemas, but the efforts of vomiting did not in the least distress her, except a little pain like smarting at the stitches close to the umbilicus.

Concluding Remarks.—A progress more satisfactory it was scarcely possible to anticipate, and with rigid attention to the rules prescribed, we had every reason to hope for a favourable termination of the case, and it is but justice to say, the patient exhibited a fortitude during the operation, and a strict determination to obey the injunctions to the very letter, that rendered success still more probable.

From the circumstance of some of the above tabulated items never occurring again during the progress of the case towards complete recovery, I shall omit them in the subsequent tables, such as coldness, disturbed respiration, hæmorrhage, shivering, and light-headedness; should any other item be omitted it will be from the same cause.

The second table continues the case to the conclusion of the fifth day, when the first dressings were removed.

Summary from the conclusion of the first twenty-four hours after operation, to the eve of the fifth day, when the incised wound was dressed for the first time, deduced from the above table.

Temperature of the apartment.—The temperature was still kept up to its usual height, as expressed in the first table.

Pulse.—The circulation though expressed in different numbers, was always soft and compressible, with one exception, when it stood at 90, and fuller, which was soon after followed by copious perspiration, when it immediately became quicker, but very soft.

Skin.—Twice in the above space the skin assumed a dry character; it was however, but temporary, neither time exceeding two hours.

Tongue.—Only became temporarily dry whilst the skin assumed that character.

Thirst.—Though seldom really absent, was never otherwise than trifling.

Flatus.—Was frequently felt, but in a trifling degree; the tube introduced into the rectum effectually emptied the bowels of all gaseous matter, when applied; the flatus had entirely ceased before the conclusion of the above table.

Pain.—During the whole space entirely absent.

Cough.—Was never distressing, disappearing after the fourth day.

Urine.—Had been drawn off by the catheter five times in the space tabulated; the full amount of fluid, fifty-one ounces. At the conclusion of the fifth day, she passed urine naturally for the first time, to the extent of sixteen ounces.

Motions.—The first motion by natural efforts was on the fourth day, and on the eve of the fifth she had three natural evacuations. Previous to the fourth day, the motions procured by clyster were assisted by a double six-tailed bandage imitating abdominal muscular action, a means that I have frequently seen effective in other cases. Where clysters have been obstinately retained, it is necessary to apply the bandage about five minutes after the exhibition of the clyster, and instruct the patient to assist by bearing down a little and holding the breath.

Sleep.—The extent to which she enjoyed refreshing sound sleep in the last four days, was remarkable—not being less than twenty-five hours, which, added to the six hours and ten minutes in the first table, makes a total of thirty-one hours and ten minutes.

Vomiting.—Was never distressing, and finally disappeared on the eve of the second day after the operation.

Wound, Dressing.—On removing the dressings, the wound looked remarkably well, and with the exception of half an inch near the umbilicus, and about the same space near the pubes, where the ligatures of the pedicle and vessels came outward, the whole had adhered: the patient experienced little fatigue from the dressing and changing the bed and linen; it was with difficulty she was restrained from giving a helping hand.

ORFILA'S LECTURES ON ARSENIC.

Containing an Account of the different Operations performed upon the Body of Laffarge.

Collected and Translated by JOHN DAL PIAZ, Pharmacien and Laureate of the School of Paris.

Lecture VIII.

Gentlemen,—I terminated my last lecture in speaking of Monsieur Rassori's ideas with respect to arsenical toxication. Monsieur Rogetta, who adopts the same opinions, has endeavoured to render them popular in France; he considers arsenical intoxication as an asthenia, and proposes, as a curative method, the use of broth and brandy. I established, in my first memoir the advantages derived from bleeding in cases when a powerful reaction occurs. This mode of acting has been strongly criticised by Monsieur Rogetta, who asserts that, by bleeding we increase the effects of the poison, and consequently the life of the patient is sacrificed. Finally, this gentleman wrote to the academy of medicine, requesting they would name a committee to examine these two modes of operating in experimenting upon animals.

This request was also made by myself; in consequence of which a committee, composed of Messrs. Oliviers d'Angers, Amussat, Lecame, Bouillaud and Husson, was named. The experiments were continued during four months, in which time forty dogs were poisoned and submitted to the two modes of treatment: some were bled, while to the others was administered broth and brandy. A certain number of the dogs vomited, and, I must confess, almost all those who were bled died, whilst one-half of those who had taken the tonic mixture (broth and brandy) recovered.

Such were the results presented to the academy by Monsieur Olivier d'Angers who, at the same time, declared the experiments had been badly conducted, and that vomiting ought to have been prevented by tying the œsophagus. This operation had been proposed, but Monsieur Rogetta was opposed to its being practised; nevertheless, the Royal Academy, from these results, encouraged Monsieur Rogetta to continue his experiments. In consequence of these having been badly conducted, I requested they might be repeated in a different manner; it was my opinion that vomiting ought to be prevented, as dogs are not easily poisoned with arsenious acid on account of the facility with which they eject the poison. It is, therefore, indispensable, when such experiments are to be properly conducted, that a ligature be applied to the œsophagus after introducing the poisonous matter. The following results confirm what I have already stated respecting these operations.

1. If arsenious acid is administered to a dog, and the œsophagus is afterwards tied, death is sure to result.

2. If to another dog the œsophagus is tied and no poison has been administered, death will not result; when the ligature is removed, the animal will eat and drink as usual, although the œsophagus had been tied for 24 hours.

It was in consequence of my insisting upon these two facts that the academy appointed another committee which during a great length of time (19 months) did not assemble once, and consequently made no experiments. Nevertheless it was asserted, in a certain public paper, that our mode of treatment hastened death in a striking manner; that the first committee had declared it to be attended with dangerous results, and gave their preference to the treatment by tonics.

Being, however, fully convinced of the superiority of my method, I was induced to try a great number of new experiments from which I conclude: if a dog poisoned with 25 centigrammes of arseni-

ous acid can vomit after a certain quantity of water has been administered, he will recover.

If, on the contrary, after the introduction of that same quantity of arsenious acid, the ligature of the œsophagus is performed, death is sure to result.

I have also repeatedly tried the treatment by tonics, and have found death ensues much sooner, provided the œsophagus is tied. These results induced Monsieur Rogetta to repeat his experiments upon horses, who, as we know, have not the power to vomit.

Only one out of 14 of the horses poisoned, and afterwards treated by tonics, died: several others were bled, and of these only two were cured.—There is nothing very extraordinary in this; I never said that good effects were always produced by bleeding, but I stated it should be resorted to when there are signs of a powerful reaction. It is the intention of the academy to repeat the experiments upon dogs: I am confident if these are properly conducted, the result will prove the truth of what I have before stated, and which I again repeat. If a dog vomits immediately after taking the poison, death will not ensue, and I persist in saying the treatment recommended in my last lecture is the most rational; and that it is indispensable in cases of poisoning by arsenious acid, to evacuate the poison by vomiting. I also again assert that the Italian mode of treatment ought not to be adopted.

In the preceding lecture, I mentioned the property hydrated peroxide of iron possesses to combine with arsenious acid, and I recommended its use in cases of poisoning by this substance; the experiments of Messrs. Lesueur, Sandras, Monat and Deville upon dogs; and those of Monsieur Bouley upon horses, together with the several cures effected upon man, leave no doubt of the efficacy of this chemical agent. An objection to the use of this antidote may be that it sometimes contains a minim portion of arsenious acid. It may be asked whether, in this case, the administering of such an antidote would not severely aggravate the state of the patient? The following experiment is sufficient to prove that such a peroxide of iron may be used with perfect safety.

Four ounces of an arsenical peroxide of iron were administered to a dog, and the œsophagus afterwards tied. From this treatment no poisonous effects resulted. I then destroyed the same dog by hanging him, and although the strictest research was made to detect the poison in the organs, none could be discovered. This may be easily accounted for. We have only to reflect upon the infinitesimal quantity of the poison in combination with four or six ounces of the peroxide. That absorption could not occur is evident from the chemical influence exercised by such a large excess of peroxide of iron, and Berthollet has sufficiently proved the influence of masses, with regard to chemical decomposition, to admit of our assertion respecting arsenical peroxide of iron. It may, however, be easily ascertained by Marsh's apparatus whether the peroxide of iron is arsenical or not.

I shall now discuss another point relating to this subject, and which may at first seem rather complex and difficult. I will suppose an individual to have been poisoned by arsenious acid, and the medical attendant has administered peroxide of iron. Nevertheless, the patient dies a short time after this antidote has been employed, and at the *post mortem* examination the peroxide is found in the digestive tube, consequently, when analyzed with the other matters contained in the stomach, &c., arsenic will be obtained, and the experimenter, who knows perfectly well that the hydrated peroxide of iron may have been arsenical, is greatly embarrassed to discover whether the arsenic proceeds from the peroxide, or from arsenious acid purposely administered. Experience has solved this difficulty. If arsenical peroxide of iron found in the digestive canal does not leave arsenious acid in solution, after having been boiled a long time in distilled water, it may be asserted, if it yields arsenic by other means, that the poison proceeds from the impurity of the peroxide; if, on the contrary, this has combined with arsenious acid already in the stomach, the arsenious acid thus united to the peroxide would have been retained in the boiling distilled water, which, nevertheless could not extract the arsenious acid naturally contained in the peroxide of iron. Again, add the suspected peroxide to a solution of caustic potash; this alkali, although it will not eliminate the poison naturally combined, will certainly extract that which has been recently neutralized by the same peroxide, provided the arsenious acid does not exist in too minute a proportion. The arsenite of potash thus obtained may be immediately detected, either by sulphuretted hydrogen, or by Marsh's apparatus.

Gentlemen, I think I have now refuted all the objections which can possibly be offered in favour of an accused: I should have completed this task of making you acquainted with my medico-legal doctrine, in cases of poisoning by arsenious acid, had I not the desire to inform you of the various operations resorted to in the case of Monsieur Laffarge.

The first medical attendant of Monsieur Laffarge was Dr. Badon: this gentleman did not suspect that poisoning had been effected, and from the nature of the matters ejected, he thought the complaint was a volvulus.

On the 13th of January, 1840, Dr. Lespinasse was called to attend the patient: he expresses himself as follows:—

"Upon my arrival, I found Monsieur Laffarge pale and thin; he complained of constriction in the throat, the bottom of which appeared red and inflamed; he was much exhausted by continual vomiting, and frequent hiccups; all his extremities were cold, the circulation scarcely sensible, and the beatings of the heart quite disorderly; syncopes occurred at intervals, and were followed by continual agitation. From these symptoms," adds Monsieur Lespinasse, "I did not hesitate to think Monsieur Laffarge had been poisoned; I consequently administered peroxide of iron."

Without doubt, this doctor was fully convinced that the symptoms were such as to justify him in making so positive an assertion.

The patient died on the 14th of January; and, upon opening the body, the stomach was found to be inflamed, and to bear several ecchymoses; the duodenum had a real gangrenous stain, and the valves of the heart were more coloured than usual. A medico-legal examination was then ordered by the judiciary authorities, to be made upon a "lait de poule,"* which yielded a very small quantity of arsenic.

Several other liquids were afterwards examined, and those treated with a few drops of a solution of sulphuretted hydrogen, yielded a yellow precipitate of sulphuret of arsenic. The eighth analysis was that of the liquid contained in the stomach, together with a decoction of a portion of this organ: the liquid thus obtained, acidulated with hydrochloric acid, and afterwards submitted to the action of sulphuretted hydrogen, afforded a yellow precipitate of sulphuret of arsenic. Metallic arsenic was not obtained, in consequence of an accident which occurred during the analysis of the sulphuret from which it was to have been eliminated; the tube, in which was contained this compound, mixed with charcoal and carbonate of potash, burst,—the extremity having been, by inadvertance, hermetically sealed.

Nevertheless, the experimenters concluded to the presence of poison, although they had not obtained it in the metallic state. I have already said this conclusion ought not to have been offered before they had obtained the metal.

Other experimenters analyzed the fourth part of the stomach, which had been preserved in alcohol: this was carbonized by nitric acid, but the charcoal thus obtained offered no positive results. Another portion of the stomach was boiled in distilled water, and the filtred decoction submitted to the action of various tests, such as nitrate of silver, sulphuretted hydrogen, &c. &c., produced no positive results. Then the matters contained in the stomach were submitted to the action of Marsh's apparatus without effect.

In consequence of these operations being attended with negative results, the body was ordered to be exhumed, that other experiments might be performed upon the liver, the heart, and a portion of the intestines. These were carbonized, and a filtred decoction of the charcoal obtained was submitted to the action of Marsh's apparatus: in this case, again, the presence of arsenic was not detected. Nevertheless, Dr. Lespinasse was still convinced, from the symptoms observed upon Monsieur Laffarge during life, and from the lesions observed at the *post-mortem* examination, that poison had been administered; he assures, us the jet of inflamed gas was nearly two inches long, and we know that under this condition metallic arsenic cannot be condensed upon the capsule: however, he also says, he obtained two arsenical stains, towards the end of the experiment.

The judiciary authorities having decided upon further investigations, Messrs. Olivier d'Angers, Bussy, and myself, were requested to undertake them.

We commenced by carbonizing with nitric acid the part of the stomach remaining, the matter ejected, and the liquids found in the digestive tube: the charcoal we thus obtained was boiled in distilled water, and the filtered decoction introduced into Marsh's apparatus. From this experiment we obtained a small quantity of metallic arsenic.

A second experiment was then made upon the mass of matters labelled, "Matters from the organs of the thorax, the abdomen, the liver, the heart, and the brain." Two distinct operations were performed upon this mass. We boiled the whole in distilled water during four or five hours, and strained the decoction through a cloth; this decoction was then evaporated nearly to dryness, and the residue, having been carbonized by nitric acid, produced a charcoal, which yielded about the same quantity of metallic arsenic as we obtained in our first experiment.

We next examined the solid matter separated from the decoction, and which had been carefully laid aside. This we incinerated by nitrate of potash; had we in this case used nitric acid we should have obtained a bituminous charcoal, the inconvenience of which I have before stated. The solid matter was burning during seven hours before the whole was perfectly incinerated; we then operated upon one-half of the residue, in the manner already described in a former lecture, and from this we obtained twelve times as much arsenic as in each of the former experiments. This result was so satisfactory that we did not consider it necessary to operate upon the remaining part.

A piece of flesh cut from the thigh of the corpse was afterwards examined; it was incinerated by nitrate of potash as in the preceding experiment; in this case no indication of arsenic was observed, although the flesh weighed two pounds.

A portion of the shroud in which the body was enveloped was also examined; it was boiled in distilled water, containing pure caustic potash; the liquid thus obtained yielded no signs of arsenic.

Our next examinations were upon two of the samples of earth collected; one of which was taken from under the coffin, and the other from above. These were boiled separately in distilled water during four hours; the filtered liquids, when submitted to Marsh's apparatus gave negative results.

From the preceding experiments we were enabled to conclude:

1. That arsenic existed in the remaining fourth part of the stomach, in the liquids contained in the viscera, and in the matters ejected.

2. That it also existed in the decoction made from various organs, but that the poison was most abundant in the solid matters remaining after the liquid had been separated.

3. In no other part could arsenic be detected. I may now mention, as a proof that the arsenic thus obtained did not exist in the re-agents employed, that they were the same employed by the chemists of Tulle, with the exception of the nitre. These gentlemen, we know, were of opinion that arsenic did not result from their experiments; consequently, the re-agents must have been pure. I may further observe, that previous to the introduction of the suspected liquids, Marsh's apparatus

* A popular remedy, made by dissolving the yolk of an egg in eight ounces of boiling water, then adding sugar and orange-flower water q. s.

had been in action during twenty minutes without giving the slightest indication of arsenic. The nitric acid we made use of, had been distilled upon nitrate of silver, and we know that, when thus prepared, it cannot contain arsenic. That the poison did not proceed from the soil was also quite certain, for the coffin was not all injured; it only offered a slight crevice in the inferior part: moreover the earth, when analysed, was found to be quite free from arsenic.

Gentlemen, I shall terminate all I have to say upon arsenious acid, by resuming in a few words the methods of analysis, and the mode of treatment adopted by myself.

Methods of Analysis resumed.—1st Problem.—1. Collect the grains of arsenious acid existing in the ejected matter, or deposited upon the internal parts of the digestive canal and ascertain their character.

2. Boil separately, in distilled water, for four or five hours, the matter ejected and that contained in the digestive tube; taking care at the same time to well wash the digestive tube itself. Separate the insoluble matter by filtration, and evaporate the liquids to about one-fourth of their volume; then add a sufficient quantity of pure boiling alcohol, and filter again; acidulate the filtered alcoholic liquids with hydrochloric acid and add sulphuretted hydrogen; collect the arsenical sulphuret thus formed, and submit it to further examination.

Carbonize, with nitric acid, the solid matters remaining on the filters, and submit the decoction of the charcoal to the action of Marsh's apparatus.

3. If neither of these operations have afforded arsenic, the stomach and intestines must be examined by boiling them for six hours in distilled water; the filtered decoction must then be evaporated and treated by alcohol and sulphuretted hydrogen, as before. If no arsenic is detected in this case, the stomach and intestines must be carbonized by nitric acid, and the residue examined.

Second Problem.—Carbonize with nitric acid, one half of the dried liver, and boil the charcoal produced for half an hour in distilled water; then test the filtered decoction in Marsh's apparatus. If from this operation a sufficient quantity of arsenic is obtained to remove all doubts respecting the presence of this poison, further proceedings are unnecessary.

If the result is again negative or not sufficiently satisfactory, boil the remaining portion of the liver for six hours in distilled water with the spleen, the lungs and the heart, and operate upon the decoction as before. If no arsenic is obtained, carbonise the insoluble parts of these viscera, by nitric acid.

In all cases when fatty matters are to be carbonized, nitrate of potash should be used, as in such cases nitric acid would produce a bituminous charcoal attended with great inconvenience.

Orfila's Mode of Treatment resumed.—First stage: Administer one ounce of dried hydrated peroxide of iron well triturated with five or six ounces of tepid water; if after a short time the patient vomits a part, or the whole of the antidote, a similar dose must be again administered; should vomiting not occur, it must be promoted by giving two grains of tartar emetic in five or six ounces of tepid water.

Second stage: Promote purging by administering two ounces of castor oil, and repeated "lavements;" especially, if vomiting does not occur very soon: at the same time repeat the dose of peroxide of iron.

It is quite an erroneous idea to suppose the administration of tartar emetic is attended with bad effects; the irritation produced by the evacuations is too slight to prevent the use of this valuable remedy in such cases.

Third stage: After abundant purging and vomiting, it is necessary to have recourse to diuretics for the purpose of expelling, with the urine, the greater part of the arsenious acid absorbed. The diuretic I recommend is a solution of five drachms of nitrate of potash in 8 ounces of white wine, and and twenty ounces of eau de seltz. If from this period symptoms of reaction occur, attended with fever, bleeding should be effected either by the lancet or leeches; but bleeding should never be effected in the first periods, for fear of promoting the absorption of the poison.

MESMERISM.

To the Editor of the 'Medical Times.'

Sir,—As in spite of contemporary denunciation you have from time to time given place in your valuable journal to various cases of mesmerism, detailed by Dr. Elliotson, Mr. Atkinson, and others; perhaps you will make room for the following paragraph, from the *Jamaica Despach* of the 20th August:—

"A mesmeric experiment was made at the private residence of a gentleman of this city on Thursday last, at which several physicians and gentlemen of high respectability were present, and which, we are informed by a gentleman who witnessed it, was in every respect successful. The patient, a lady, was put into the magnetic sleep by Professor Garrison; and while in this state, the painful surgical operation of removing a large excrescence from the upper eye-lid, or brow, was performed by Dr. Arnold, assisted by two other physicians, without the movement of a muscle on the part of the patient, or the least sign of pain. The patient had long desired the operation to be performed, but had not possessed the fortitude to submit to it, and she was in utter ignorance of the design of the physicians to remove the excresence on this occasion, and knew nothing of it until the whole had been done and the wound dressed, and she had been awakened from her sleep; indeed, we are told, that while the wound was being dressed Professor Garrison *willed* her to sing a favourite air, which she immediately did."

From the high moral and intellectual character of the editor of that paper, you may place implicit reliance on the statement, though I very much regret that one or two of the names of "gentlemen of high respectability," together with those of "the several physicians," who are said to have been present, have not been given. It is possible that this report may have appeared in other Kingston papers, particularly in that very talented journal, the *Royal Gazette and Jamaica Standard.* But, as I do not see the Jamaica papers regularly now, I am unable to send you any other account of the operation than that contained in the paragraph above. Had the names either of Drs. Fergusson, or Magrath, or Spalding, or Chamberlayne, or Garicia, or Morales, or Adolphus, and last, not least, of the very learned, experienced and estimable Bancroft, the present Inspector General of Hospitals in Jamaica, been appended, such a proceeding would have stamped a medical authority upon the case, which I am content to take *only* on the authority of the editor of the *Jamaica Despatch;* "Professor" Garrison being unknown, and the operator *known* to me.

I am, Sir,
Your obedient Servant,
E. BINNS, M.D.

Montague-street, Portman-square.
11th Oct. 1842.

Remarkable Case of Ascites.—A woman, aged 36, was attacked in 1823, by a chronic entero mesenteritis, accompanied by marasmus, suppression of urine, and irregular menstruation. By degrees the abdomen became of enormous size, from the presence of fluid accumulated in the cavity of the peritoneum. The first tapping gave issue to twenty pounds of a lemon-coloured limpid fluid; and M. Lecanus ascertained, after the sinking of the abdomen, that it contained enormous indurations. Ten days afterwards she was again tapped, and so rapidly did the fluid accumulate, that it was necessary to repeat the operation every six, eight, ten, or at the utmost twelve days. Fifteen years had elapsed in this manner, and tapping had been performed 810 times, when Dr. Lecanus thought of trying compression on the abdomen with pieces of paste-board covered with linen. This remedy, employed gradually, at first retarded the accumulation of the fluid; and at the end of six months, during which time tapping was practised at more or less distant intervals, it was perceived that the ascites no longer returned. The patient has now been completely cured these two years, having undergone tapping 866 times during 15 ar 16 years. Once only the epigastric artery was opened; but the hæmorrhage was promptly stopped by tents steeped in a styptic liquid, and introduced into the wound made by the trocar.

Diseases that never Co-Exist.—The typhus abdominalis (that is, with formation of of the characteristic typhous matter, is excluded by the various forms of puerperal fever. In two hundred dissections of puerperal fever he did not find one complication of the typhous process. This immunity from typhus is given by the pregnant, child-bed, and even, though in a less degree, by suckling.—Typhus and cholera, and typhus and dysentery, are said to have the power of mutual exclusion; and the co-existence of tuberculous disease and typhus is extremely rare. Carcinoma and tuberculosis (i.e., tuberculous disease) are antagonist diseases; and the latter, and all kinds of serous cysts, are never met with simultaneously in the same organ, or even in the same person. Tubercular disease affords an immunity from cholera, dysentery, hypertrophy of the heart, curvature of the spine, dilated bronchia, and almost all chronic diseases of the stomach. Tuberculosis and aneurism do not co-exist, and Rokitansky, as well as others, has remarked, that the development of tubercle is arrested, although the disease is not subdued, by the pregnant state, as likewise by all large tumours of the abdomen. These conclusions are derived by Professor Rokitansky from numerous *post-mortem* and other examinations.

Schirrus of the Uterus cured by the External and Internal Exhibition of Iodine.—By Dr. Zimmermann.—A lady, aged 45 years, was affected about a year ago, with a schirrous induration of the cervix uteri, to which was added a hectic fever. Dr. Zimmerman, who was called in to attend her, prescribed for her the following mixture:—℞ Iodide of potassium, 1.0 grammes; Iodine, 0.4 grammes; Distilled water, 30.0 grammes; M. and dissolve. She commenced by taking eight drops, three times a day; then the dose was gradually increased, and with great caution, until it amounted to fifteen or eighteen drops. At the same time, the physician ordered the topical employment of the following ointment:—℞ Lard, 30 grammes; Iodide of potassium, 2 grammes; Volatile oil of rosemary, 6 drops; M. S. A. This ointment was applied three times a day; sometimes to the perineum, sometimes to the inguinal regions, and sometimes, but with the greatest circumspection, to the schirrous part of the cervix uteri; in the latter case, a little while after the application had been made, mucilaginous narcotic injections were made into the vagina. After four months of this treatment, sustained without any interruption, the patient was completely cured.

Powder of Camphor and Antimony.
℞ Powdered camphor, 2 grammes; Powdered ipecacuanha, 65 centigrms; Golden sulphur of antimony, 65 centigrms; White sugar, 24 grammes; M and F. S. A. a perfectly homogeneous powder; divide into 12 doses. This formula is due to Dr. Mursinna; it is employed with marked advantage in cases of asthenic pneumonia, in chronic pulmonary catarrhal affections, when the *bronchi* are choked with

a large quantity of thick and viscid mucus, the expectoration of which is very difficult. One dose is taken every two hours, either by mixing it with a small quantity of an appropriate liquid, or by enclosing it in a piece of unleavened bread, slightly moistened with water.

PHLORIDZINE, A NEW MEDICINE.—Phloridzine is a new medicine, which is now very highly spoken of by French practitioners, as a useful adjunct to cinchona preparations, and has been used for some years in Germany, Poland, and France. It is extracted from the bark of the roots of the apple and wild cherry trees, and is thus prepared:—The bark of the recent roots is boiled with water sufficient to cover them, for half an hour. This is poured off, and the same quantity is again used; these two fluids are mixed together, and at the end of 6 hours they deposit the phloridzine, in the form of a deep red velvety-looking matter. M. Lebaudy, editor of the *Journal de Connaissances Medico-Chirurgicales*, says, "Its efficiency is so decided, that we cannot hesitate to class it with the most powerful febrifuges; and it has this advantage over quinine, that it never induces gastralgia."

PRESERVATION OF NITRATE OF SILVER.—Coat the caustic with engraver's sealing-wax, which contains a large quantity of shellac. This wax adheres well, and forms a strong and smooth varnish, as it were, which remains unaffected by the atmosphere. Thus protected the nitrate no longer stains the fingers, injures the caustic case, nor is in any way changed by the moisture in the air; it possesses a greater degree of solidity, and at the same time the process is of exceeding service in practice, inasmuch as when wanted for use, a small part only of the caustic need be uncovered by means of a penknife, so that its application can be restricted to the part where it is required. This is of peculiar utility in ulceration of the throat, aphthæ, fissures, &c.

KING'S COLLEGE MEDICAL AND SCIENTIFIC SOCIETY.—This Society resumed its weekly meetings, on Thursday evening, Oct. 13th, at 6 o'clock, Dr. Budd in the chair.

ADVERTISEMENTS.

London: Printed and Published by JAMES ANGERSTEIN CARFRAE 49, Essex Street Strand, in the Parish of St. Clements Danes, Westminster, in the County of Middlesex.—October 22nd, 1842.

THE MEDICAL TIMES

A Journal of English and Foreign Medicine and Medical Affairs.

No. 162. Vol. VII. LONDON, SATURDAY, OCTOBER 29, 1842. PRICE FOURPENCE. Stamped Edition, 5d.

For the convenience of Subscribers in remote places, the Weekly Numbers are re-issued in Monthly Parts, stitched in a Wrapper, and forwarded with the Magazines. Orders for the Stamped Edition (10s. 10d. per Half-year, Post free in advance,) are received by any Bookseller or Newsman, or may be directed to J. A. Carfrae, Esq., at the Medical Times Office, (late Lancet Office,) London.

SUMMARY.

CASES OF PERITONEAL SECTION

FOR THE

EXTIRPATION OF DISEASED OVARIA BY THE LARGE INCISION FROM STERNUM TO PUBES, SUCCESSFULLY TREATED.

By CHARLES CLAY, Member of the Royal College of Physicians, London, of the College of Surgeons, Edinburgh, and Lecturer on Medical Jurisprudence, &c. Piccadilly, Manchester.

(Continued from page 62.)

Observations.—The rapid and satisfactory progress of the case hitherto, more than realized my most sanguine expectations, still, I was aware, even in this advanced stage of the case, that the slightest carelessness might lead to a serious, if not fatal, termination; the rules prescribed therefore, were not in the least abated either to the patient or attendants. I continued to see her frequently in the course of the day up to the fourteenth after operation. In giving the last table of symptoms and attendance, I shall not record every visit, but the result of every day in each column. The items respecting the *thermometer*, pain, vomiting, cough, and flatus, will be omitted, the first (though still used) was not imperatively necessary, and the other four had entirely ceased troubling the case.

General Remarks.	Sleep	Motions	Urine	Thirst	Tongue	Surface	Pulse	
Former diet continued rigidly—Gave half a grain muriate morphine at bed-time.	7½ hours.	Two.	℥iij.	Little.	Clean.	Moist and warm	90.95.86. Soft.	Sept. 18, 5 P.M.
Complains of hunger—Allowed coffee for the first time, as a change, with former diet.	2½ hours.	One.	℥ix.	Very little.	Clean.	Moist and warm	86.86.84.	Sept. 19, 5 P.M. [illegible]
Much refreshed by sleep—Wants more tasty things to eat—same diet rigidly enforced.	10 hours.	One.	℥iij. ℥viij. ℥viij.	None.	Clean.	Moist and warm.	80.80.78.75.	Sept. 20, 5 P.M.
Dressed the wound, which looked very healthy—removed four of the stitches—the ligatures tried, but firm	5 hours.	None.	℥ij. ℥ii. ℥vi.	None.	Clean.	Moist and warm	76.76.75.	Sept. 21, 5 P.M.
She feels so well, that it is with difficulty she is kept to her usual diet—promised a change to-morrow.	7 hours.	None.	℥viij. ℥viij. ℥vi.	None.	Clean.	Moist and warm	70.70.74.	Sept. 22, 5 P.M.
Dressed the wound—all the stitches removed—ligatures not yet come away—ordered Ol. Ric. ℥ss., which operated very soon—ordered a mutton-chop, with bread, twice in the day.	7½ hours.	Three.	℥vii. ℥vi.	None.	Clean.	Moist and warm	76.78.	Sept. 23, 5 P.M.
Complained of the chop being a small one—Felt very well—sleeps sound—ordered half-sitting posture, occasionally, for change.	5½ hours.	One.	℥vi ℥vi	None.	Clean.	Moist and warm.	76.78.	Sept. 24, 5 P.M.
Feels better in health than she has done for two years—sallowness left her countenance—dressed the wound—ligature still retained—animal-food twice in the day.	All night.	None.	℥iij.	None.	Clean.	Moist and warm.	78.78.	Sept. 25, 5 P.M.
No restriction as to diet—sits up in bed.	All night.	One.	℥xii.	None.	Clean.	Moist and warm.	70.75.	Sept. 26, 5 P.M.
Continues well—greater part of the dressings dispensed with—one ligature yet to come away.	7 hours.	One.	℥xvi.	None.	Clean.	Moist and warm.	74.76.	Sept. 27, 5 P.M.
Got up, and remained up several hours—improves in strength daily.	All night.	None.	℥vij.	None.	Clean.	Moist and warm.	75.76.	Sept. 28, 5 P.M.
Sat up all day—wound required but little dressing.	All night.	None.	℥xvi.	None.	Clean.	Moist and warm.	70.72.	Sept. 29, 5 P.M.
Joined the family down stairs to-day—may be considered well.	All night.	None.	℥xvi.	None.	Clean.	Moist and warm.	70.72.	Sept. 30, 5 P.M.
Continues well—dressings almost dispensed with.	Nearly all night.	Two.	℥xx.	None.	Clean.	Moist and warm.	70.76.	Oct. 1st, 5 P.M.
Continues well—appetite good—takes a little exercise.	All night.	One.	℥xviii.	None.	Clean.	Warm and moist.	70.71.	Oct. 2nd, 5 P.M.
My patient now having resumed her household duties, and being quite well, any further notice of the case is unnecessary, although I visited her occasionally.	All night.	One.	℥xx.	None.	Natural.	Natural.	70.70.	Oct. 3rd, 5 P.M.

GENERAL OBSERVATIONS.

Thus terminated successfully, not only this formidable operation, but its subsequent treatment; a more satisfactory issue could not have been anticipated by any person who witnessed it; the simplicity of the treatment throughout was remarkable: procuring evacuations of fæces and urine, when it was thought the parts were overloaded; and a few hours sleep occasionally, when the case appeared to require it, were the only means put in practice; as little medicine as possible was exhibited for evacuations from the bowels; clysters were preferred to any purgative, and emptying the bladder, until natural efforts were able to accomplish the same. In procuring sleep, common opiates were avoided, in consequence of their tendency to constipation. The tinct hyosey., and the mur. morphine, given in combination had the best effect, but even those were given as seldom as possible. I am of opinion that nature is capable of effecting much more than she obtains credit for; and the less we interfere with her the better. I am the more convinced of this, by the plans of treatment adopted by others, particularly in the minor operation (as proposed by Mr. Jeffreson) in the case treated by Mr. Phillips reported in the "Medical Gazette," vol. 1, 1840-1, page 83, and which, in my opinion, was far too complicated. It will also be observed that I did not exhibit a brisk cathartic before the operation, as recommended by Mr. Lizars. I dissented from this plan, simply because I considered the operation of cathartics as producing a degree of irritation which I felt wishful to avoid: I therefore substituted the inspissated ox-gall, which extensive experience has pointed out to me as an excellent solvent of the fæcal matter of the intestinal canal; and by the solution, its propulsion is facilitated without producing the slightest irritation. This remedy appears also to have a peculiar effect of ridding the intestines of flatus, a matter of great consequence in such an operation, and it was in this case, remarked by many medical gentlemen present, how void of flatus the intestines were; by which the operation was very much facilitated. In applying more interrupted sutures than Mr. Lizars, I merely adopted a hint thrown out by that excellent operator, that it was better to have plenty than too few; which, with the precaution of marking the parietes, as before stated, rendered eversion of any part of the incised wound impossible. Why the incision should not pass directly through the umbilicus may be asked with propriety? My own opinion is, and probably it was the opinion of Mr. Lizars, that the wound would be less inclined to heal (if through the umbilicus); in the case just related the last part to heal, with the exception of where the ligatures passed outwards, was in the vicinity of the umbilicus. In all operations of this kind however, I should keep strictly to the linea alba except at the umbilicus, which I would leave to the right or left about half-an-inch, coming to the linea alba again as soon as possible. So long as the dressings continue in good condition, there ought to be no hurry in removing them. In this case, the fifth day had concluded before the first dressings were taken off and then with great caution, lest the patient might take cold; it is therefore necessary the temperature of the room should be attended to, at the time, as well as in subsequent dressings, as there is considerable exposure. On examining the tumour after its extirpation, the portion lying in the pelvic cavity was in a state of ulceration, it was therefore fortunate the operation took place, had it been delayed the result might not have been so satisfactory, and as the weather began to be cold about the 21st of September, an artificial temperature must have been substituted, which might not have been so easily manageable, particularly as the operation was performed in a small cottage room, where the least inattention might produce a great alteration in the temperature. On the morning of the third day after the operation, flatus became troublesome for the first time, which was effectually removed by the introduction of an elastic gum tube a few inches up the rectum; a plan I should earnestly recommend as effectual without producing any irritation. In expelling the flatus, as well as the clysters, considerable assistance was given by a sixtailed bandage crossed over the abdomen, imitating the action of the abdominal muscles. The most rigid principles were adopted as to diet, and on this, I consider, much of the credit of the cure depended. I was of opinion that in such cases the principle of stimulants, whether as medicine or diet was injurious; I therefore adopted the simplest matters for food and drink I could think of. Boiled bread, bread out of toast water, toast water, gum mucilage, thin arrow root, gruel, and German rusks softened in toast water were rigidly enforced for the first six days, and up to the twelfth day, only boiled rice, a little milk added to the arrow root, and a little weak tea were added; so that my patient complained more of being starved than otherwise. When I look back at the many circumstances which might be deemed unfavourable to the case here recorded, I am the more convinced of the propriety of this operation in preference to the minor one proposed by Mr. Jeffreson. My patient was old, the period of cessation of menstrual discharge, with its many bad consequences (though it had not taken place) might reasonably be expected to interfere with the cure; adhesions existed; the tumour was large, the pressure had produced ascites, ulceration had commenced in the pelvic mass; there was one large cyst combined with six or seven smaller ones; the cysts were also combined with nearly seven pounds of a consolidated mass of cartilaginous and fibrous texture; and lastly, my patient was worn down by long disease, emaciated, and distressed in spirit, before relief was proposed by an operation. In these symptoms there are some points so decidedly opposed to the mode of operation as proposed by Mr. Jeaffreson, that I cannot avoid drawing a comparison. If it were positively certain, that the ovarian tumour was composed of only one, two, or even three cysts, provided they could be defined, and punctured, if it were equally certain that no adhesions existed beyond the pedicle, and if we could be assured no part of the tumour was consolidated, then I should say that the minor operation of Mr. Jeaffreson would be the only justifiable one, but if any one of these objections exist, I am decidedly of opinion that we had better let the patient alone. The fatality shewn by the results of those operations in almost every person's hands, with the exception of Mr. Jeaffreson, and once by Mr. King, fully justify the remarks I have just made upon it. It would be difficult to puncture more than one cyst, it would be impossible to draw the cyst through a small opening if adhesions existed, without doing irreparable mischief; it would be equally impossible to extract, through a small opening unpunctured smaller cysts, or a portion of consolidated tumour. The question then is, are these objectionable points frequent? Mr. Phillips says, "That more than one cyst may exist in the same tumour at the same cannot be denied; but although it may be it is rarely the case." I am afraid this conclusion has been drawn too hastily; the number of cases of punctured ovarian cysts, is too few to warrant to general a conclusion: the case I have here reported is contradictory to this view. Two of the cases of Mr. Lizars had more than one cyst, and from specimens of post-mortem extraction of diseased ovaria, I believe, the fact of more cysts than one in the same tumour, to be more common than Mr. Phillips supposes. I think he would have been more correct in stating, that generally there is one very large cyst, and more or less smaller ones. Again Mr. Phillips observes, "*The coexistence of a solid tumour and a large cyst, I do not deny that it may happen, but I do maintain it to be a rare exception.*" In my case the solid part of the tumour was equal in weight to the saculated part with its contents. I have a post-mortem specimen where the solid part is equal to the sac. Some of Dr. Macdowal's cases of Kentucky, as well as Mr. Lizar's I believe possessed similar features. Lastly, Mr. Phillips asserts, "*That adhesions are frequent.*" On the contrary, Dr. Seymour in his excellent work states, that adhesions exist in ninety-nine cases out of the hundred; both assertions, perhaps, are too much in the extreme; but one more moderate might have been made *that adhesions very commonly exist*; I have never yet seen a case entirely free from them. Now let the reader suppose a case of more sacs or cysts than one or two, or of one with a large consolidated mass with or without cyst, or one with adhesions, though not extensive and then let him imagine himself employed in bringing this tumified mass away by dragging it through a small opening of one and a half or two inches. I certainly should not envy his position, the tearing asunder these adhesions, the difficulty of puncturing a number of cysts, the tearing and enlarging the outward incision by the force required, and lastly, the impossibility of bringing such a mass through so small a space; all of these, or any one of them existing, or the bare possibility that such might exist, is sufficient to condemn the mode of extraction by small incision; and how are we to know that these do not exist? Every person who has paid attention to the subject, knows how very obscure the symptoms of ovarian disease often are, and how very difficult it is to form a correct diagnosis as to the particular state of the tumour; adhesions have been found where none were anticipated, and they have been absent when confidently expected. It is often difficult to say to which side the pedicle is attached, equally difficult to say if the tumour contains one or more cysts, and impossible to tell if any part of the tumour be consolidated or not. By the large incision, whatever difficulty presents itself, we are prepared for it: it matters not which side the pedicle may be, there is plenty of room for cutting asunder the adhesions, however numerous, the whole mass may be removed entire without puncturing the cysts, thus avoiding the disagreeable circumstance of the fluid of the cyst escaping into the abdominal cavity; perhaps, one great cause of death in the minor operation and lastly, we have now abundant proof that peritoneal inflammation is not a whit more excited by a bold opening, than by a smaller one. It must also be borne in mind that the tearing away of the adhesions, *unless very recent ones*, is entirely avoided by the operation of the large incision.

The principal opposition to the large incision, as practiced by myself, Mr. Lizars, and Dr. Macdowal, consists of prejudice, and too much dread in making openings into the abdominal cavity; but time and a few more successful cases will soon overcome both the prejudice and reluctance of surgeons on this subject, and

if I am not mistaken, a new era is opening upon us, as to operations on the abdominal and pelvic viscera. One thing is certain, we can make an opening of any extent, and explore the viscera without any more danger of inflammation than *might follow* the most trifling puncture of the peritoneum. For myself, I feel I should be justified in making extensive incisions into the abdominal cavity, for other objects than the one here related. I would ask what should prevent the spleen from being extirpated when diseased? Or fatty tumours of the omentum? Or tumours of the fundus uteri? In fact, what has been done, is enough to enable me to declare the large incision operation for extirpating the diseased ovaria, *a perfectly legitimate operation*; more successful than the one proposed as its substitute, and, that ere long, operations will be performed on the abdominal regions, hitherto unknown in operative surgery, and with safer results than heretofore. The celebrated Lizars says, "*On considering the nature of serous membranes, it appears, they are less prone to inflammation than cellular tissues which are more confined, or shut up. The exhalation, which is perpetually going on, seems to moderate action, which is strikingly illustrated by dropsy of the tunica vaginalis testis, where the greatest difficulty is experienced by the surgeon in producing inflammation sufficient for adhesion.*"

After operations of this nature, the danger is in the first twenty-four hours; first from haemorrhage from the secured vessels, and secondly, from peritoneal inflammation, which can easily be checked if bleeding be timely resorted to; *but if neglected*, death is almost certain. In my case, the pedicle was rather thick, and the only drawback attending this, is, that the ligature may not be sufficient to stop the bleeding of the vessels contained in it, for supplying the tumour, and thereby requiring ligatures on the vessels themselves. Dr. E. T. Seymour in his excellent work on the diseases of Ovaria, makes the following observations:—

"These considerations have led to the recommendation of a similar operation, when the disease of the organ has attained a size which leaves little other hope of relief by human art. It has recently been successfully performed several times on the Continent, and in our own country, by Mr. Lizars of Edinburgh. Nevertheless, the arguments against such an operation are numerous and strong; and the probabilities of success are very small. If the tumour be not large, and the woman's health unbroken, she may live many years, as long as is allotted to humanity in the enjoyment of a tolerable existence. If the health be much broken the cure of so large a wound in a weakened constitution would be difficult, if not in the great majority of cases, impossible. If connected with schirrus in other parts of the body, it is inadmissible; and if the growth itself be of the nature of fungus haematodes, all experience tells us that should the operation be survived, or the wound heal, the disease will recur in other vital organs of the body. Nor do the difficulties rest here, when these growths enlarge to a great size, they most frequently adhere, and here the operation is out of the question. If all these exceptions then, are estimated, the case which remains in which such a risk is advisable, and such an operation feasible with any fair chance of a happy result, is rare indeed. Still the meed of praise cannot be withheld from those men who have dared, and been successful."

In respect to the above observations, I need only observe, the operations already performed, their uniform success (I mean by large incision) shew the arguments against it are neither numerous, nor strong. In my case the tumour was large, the health broken, and yet the cure of the wound was not difficult; in my case, adhesions existed, yet the patient did well. I cannot but refer particularly to the opinion of Dr. Seymour, in respect to the prospect of a "female enjoying a tolerable existence with unbroken health, and living an average life with a tumour of even moderate dimensions," in which I cannot entirely agree with him. In a great majority of cases, even when the tumour is small, the hopeless advice they have been in the habit hitherto of obtaining from medical men has rendered their lives often truly miserable, and in all cases far from being enviable. There are some cases recorded of simple tapping in ovarian dropsies, without attempting the removal of the cysts; some of these are remarkable for the quantity of fluid evacuated; one is mentioned by S. S. Brame, (see the first number of vol. vii. 'Medical Times,') in which was removed, at ten operations, the enormous quantity of 73 gallons and 5 pints of fluid. I am inclined to believe that there has not been sufficient distinction in many of these cases, as to whether these great quantities of fluid are really obtained from cysts, or from the abdominal cavity itself, in the character of ascites produced by the pressure of the tumour interrupting the proper functions of the abdominal and pelvic viscera. I do not say Mr. Brame's case was the true ascitic fluid, but I suspect many cases are recorded where the fluid is stated as from an ovarian cyst, which is really taken from the abdominal cavity, independent of the sac of an ovarian tumour. There is a material difference between ovarian disease accompanied *with ascites*, and dropsy confined *particularly to the sac of an ovarian tumour*. If the case be ascites, with or without ovarian disease, tapping is highly proper; but it is more questionable if tapping should be so *generally resorted to* in ovarian encysted dropsy, simply because it is only a very temporary relief, as long as the sac is still retained, and adhesions are more likely to occur where the tapping is effected from time to time, rendering operations for extirpation, *by any mode*, more serious and difficult. Whilst I was recording these remarks, a person applied to me with the abdomen distended with ascitic fluid; the whole features of the case and the history of it, presented the character of ascites. I tapped her to the amount of twenty-nine pounds and a half of fluid, having the true ascitic character. When the whole was evacuated, I found a tumour on the left iliac region, about four pounds weight. I do not consider this case as ovarian dropsy, or that the water discharged was taken from an ovarian cyst, but that it was a case of ovarian disease, accompanied with ascites; the latter produced by the interference of the tumour with the visceral functions. In the case of Mrs. Wheeler, (here detailed at length) between six and seven pounds of ascitic fluid presented itself from the same cause, but which had no connection with the ovarian mass of cysts, as the whole of them were afterwards *removed entire*. In respect to the connection of ascites with ovarian disease, Mr. Lizars remarks, "Again, diseased ovarium is frequently accompanied with ascites; so that in our treatment, when we are aware that there is ascites, and suspect a diseased ovarium, *we should first perform paracentesis abdominis.*" I am inclined however, to differ in opinion with this celebrated surgeon, believing that peritoneal inflammation would be more likely to occur from the operation by incison and consequent exposure of the viscera, *if paracentesis abdominis had been previously performed*, because some excitement of inflammatory action would have occurred in healing the tapping wound; which, though it might be slight, still, might the more easily be excited again. *I think it therefore, safer to perform the operation of extirpation at once, allowing the ascitic fluid to come away at the same time.* In the case of paracentesis abdominis, which I have just mentioned, I certainly should not have performed that operation had I been positively certain of the existence of a tumour; but as neither the history of the case, nor present examination, pointed out such a circumstance as probable, I acted accordingly. The case of Mrs. Wheeler bears out the fact as already advanced by Mr. Lizars, that the most formidable adhesions to be met with in ovarian tumours, are omental; in this case, a vessel of moderate size was so connected with the tumour, as to require securing when cut asunder. The pedicle, as I expected from the history of the cases of various authors, I found to be simply the broad ligament of the uterus, which with the fallopian tube, were of considerable thickness, so much so, as to interfere with the security of the vessels contained in it to supply the tumour, requiring them to be separately secured; this, future operators should carefully bear in mind. Mr. Lizars also recommends, if the long incision give not room sufficient for the tumour to be extirpated, to make a transverse incision. *I presume he means towards that side where the pedicle is expected to be found.* I am not prepared to say whether this be necessary, but am inclined to think that there is no tumour capable of being held within the parietes abdominis, but what might be extirpated through an incision from the ensiform cartilage to the pubes.

There is one circumstance that deserves particular notice, since it tends to show the great obscurity which often exists in ovarian disease; in three instances, operations have been performed on individuals supposed to be labouring under ovarian disease to a considerable extent; and yet, when the abdominal cavity has been opened, no tumour could be found; and this has happened in the hands of first-rate surgeons, and of great experience in ovarian diseases. One is recorded of Dr. Dohlhoff, a second by Mr. King, of Saxmundham, Suffolk, and a third by Mr. Lizars, who candidly observes, "The reason why all of us were deceived in this woman's case, was, the great obesity and distended fulness of the intestines, together with some protrusion pubic of the spine at the lumbar vertebrae. This did not appear at all conspicuous before operating, otherwise it should, and must, have struck some of the medical gentlemen present who examined her; *nor did it occur to myself during the operation, nor until some time after*, when I could find no just cause for being so singularly deceived." Mr. King when not able to find the tumour after the incision, regrets that he did not raise his patient out of the horizontal position, as the tumour generally appeared in the standing or sitting posture before the operation.

Such circumstances tend to show how difficult it is to form a correct diagnosis. It does appear to me most singular that the circumstances to which Mr. Lizars attributed his being misled, were not fully and satisfactorily developed to him during the operation if they existed, for he says, "*nor did it occur to myself during the operation, nor until some time after.*" A circumstance analogous to these, presented itself to me since the operation on Mrs. Wheeler. A female called upon me respecting a tumour which she said she had in the abdomen, and which she was very anxious to get extirpated, stating that she had been troubled with it for upwards of two years. When in a standing position, the abdomen appeared much tumefied. I carefully examined the abdominal

surface, but no tumour could I find; on expressing myself to that effect, she appeared disappointed, so determinedly had she made up her mind to have it extirpated. I then caused her to sit up and subsequently to stand; in both these latter positions, the belly became tumefied irregularly in the form of an arch, the apex of which was situate above the umbilicus, whilst the origin and termination were in the iliac regions; on handling it, it disappeared (that is by pressing it). I looked upon this case as one of confined flatus, and not of tumour, though it is possible I may be deceived; but certainly no persuasion could induce me to operate for tumour, although my patient is still convinced there is a tumour, and presses me to remove it. In many cases of ovarian disease of long standing, the constitution suffers severely, and becomes so worn down, as to furnish plausible arguments against any attempt at extirpation. This, I am of opinion, has been carried too far; no person could scarcely present worse features in this respect than Mrs. Wheeler, and yet she recovered without a bad symptom. It is questionable if these depreciated constitutions do not present less liability to peritoneal inflammation than others.

Looking at all the circumstances connected not only with the operation by large and small incision for diseased ovaria, but in all operations that have taken place in respect to the abdominal cavity, where the peritoneum has been cut, there is abundant evidence to prove that the peritoneum is not by any means so disposed to take on inflammatory action, as has been generally supposed; and this simple fact in itself, may create a great change in abdominal surgery. Hitherto extirpation of diseased ovaria by the large incision particularly, has been held as highly speculative and improper; but surely the results that can now be shewn, must at once and for ever, settle the question, and establish it as a perfectly legitimate and more than ordinarily successful capital operation, as I shall more distinctly prove at the conclusion of this paper (that is), if medical statistics are to be relied upon at all. When compared with the results of other capital operations, lithotomy, lithotrity, and even amputation, it stands in a far more favourable position, and it is a very strange prejudice indeed, that can admit those capital, and more frequently fatal operations, above mentioned *as legitimate and advisable* whilst one less fatal is summarily condemned, and forborne to be mentioned in the instructions to the rising faculty. I think I have said enough to prove, that preference ought to be given to the operation by large incision for the extirpation of diseased ovaria; the very great obscurity hanging over the many circumstances connected with the tumour are only safely to be met, by the free incision; to to attempt the minor operation and meet with those features *known to be frequent*, must compel the operator to resort to the large incision, under the unfavourable circumstances of a partly emptied tumour, fluid escaped into the abdominal cavity, and adhesions lacerated; or the dreadful alternative, death to the patient without an attempt to relieve.

It is to be hoped that the prejudice hitherto existing against this rare and formidable, but successful operation, will cease; and that it will in future be classed where its merits have proved it to be worthy.

(To be continued.)

INSPECTORSHIP OF ANATOMY. The dismissal of Dr. Somerville has been followed by the appointment of Dr. A. Wood, as inspector of England, and Messrs. Bagot and Rutherford Alcock, as inspectors of England and Wales. We were mistaken, with reference to the appointme[illegible] Sir J. Graham's private physician

APPENDIX

TO

ORFILA'S LECTURES ON ARSENIC.

Collected and Translated by JOHN DAL PIAZ, Pharmacien and Laureate of the School of Paris.

Conclusions of the Report of the Academy of Sciences, referring to the Poisoning by Arsenious Acid. Commissaries: Messrs. Thenard, Boussingault; and M. Renaud, reporter.—1. Marsh's method can easily detect one millionth part of arsenious acid existing in a liquid: arsenical stains may even begin to appear when a liquid contains no more than a two millionth part.

2. The stains are not rendered more evident by a large quantity of liquid than by using a small quantity; it being understood of course, the same quantity of arsenious acid to exist in each; but in the first case the same amount of stains is produced after a greater length of time than would be required by using the more concentrated of the two solutions. Thereby results the advantage in concentrating the arsenical liquid; as by operating upon a small volume, stains of a more substantial character may be obtained.

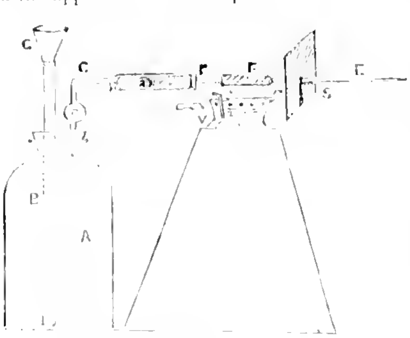
3. It is of the highest importance, when using Marsh's apparatus for the purpose of detecting arsenic, to force the gas through a tube filled with asbestus or cotton, which is necessary to retain the minute portions of the zinc solution always carried mechanically away by the current of gas; otherwise the operator may subject himself to error, as in this case there may be produced stains of oxisulphuret of zinc which have often a resemblance to those of arsenic.

4. The procedure of Monsieur Lassaigne is capable of producing good results. This consists in passing the arseniuretted hydrogen through a perfectly neutral solution of nitrate of silver, and again decomposing the liquid by chlorhydric acid; then filtered, evaporated to dryness and the residue tested as for arsenic. This same procedure is also very convenient, by enabling us to introduce into a small quantity of liquid a minute portion of arsenic existing in a large quantity of fluid, which cannot be concentrated by evaporation, thereby enabling the operator to obtain much better characterized stains by introducing the liquor into a very small apparatus. One must be careful not to conclude that arsenic exists in the liquid because the solution of nitrate of silver happens to become turbid, and produces a sediment during the passage of the gas. Similar results may be produced by non-arseniuretted gases mixed with hydrogen, or even by pure hydrogen alone, under the influence of light.

A solution of chlorine or of an alkaline chloride may be substituted for that of nitrate of silver.

5. The method of disposing the apparatus, as indicated by Messrs. Berzelius and Liebig, and usefully modified by Messrs. Kæppelin and Kampmann of Colmar, will render sensible such minute quantities of arsenic as are not manifest, or only doubtfully so, by the ordinary method of stains; such a disposition of apparatus has also the advantage of condensing more completely the arsenic, but it will often happen that this metal will be found mixed with a portion of sulphuret of arsenic which may alter its colour; particularly if the arsenical substance exists only in minute quantity.

Your commissaries have given the preference to this last disposition for isolating arsenic: they think the apparatus is best disposed as follows:—



A is a wide-mouthed glass vessel having a bung, pierced with two holes; through one of these passes a straight glass tube, B, about one centimeter (half an inch) in diameter, and reaching to the bottom of the vessel; through the other hole passes the tube C, of small diameter and bent to form a right angle. This last tube terminates in a larger one, D, filled with asbestus and about three decimeters long (11 inches): a tube, E E, of the least fusible glass, and about two or three millimeters (1 millimeter is equal to one twenty-fourth part of an inch) in diameter, is fixed to the extremity of the asbestus tube and terminates at its furthest extremity in a very fine point similar to that of a blowpipe. This tube, which should be several decimeters in length, has a ribbon of sheet copper, F, coiled about the part near the asbestus tube. This sheet copper should not extend to more than one decimeter.

The glass vessel is selected of such a size as to contain all the liquid to be examined, leaving, at the same time, an empty space equal to about one-fifth of its total capacity. Nevertheless, it should be born in mind, that the volume of the liquid should not be too considerable, if it contains only traces of arsenical matter.

The tube through which the gas escapes from the vessel has its vertical extremity a little flattened, and upon any part of its outer vertical branch a ball, O, is blown; this last arrangement is not indispensable, it is however convenient, as in this case nearly all the liquid carried into the tube by the current of gas, becomes condensed and falls back again into the vessel.

The apparatus being thus disposed, a few strips of zinc are introduced into the bottle with a sufficient quantity of distilled water to cover the bottom of the safety tube, B; a small quantity of sulphuric acid is then added. Hydrogen begins immediately to form, which is allowed to pass for some time before the arsenical liquor is introduced; this is for the purpose of clearing the vessel of atmospheric air.

The part of the tube which is surrounded with the copper foil is then made hot by means of incandescent charcoal placed upon a chafingdish V; a small screen S is so adapted as to prevent the tube being heated at too great a distance. The suspected liquor is then introduced into the apparatus through a funnel G having a small termination, in such a manner that the liquor may slide down the side of the safety tube—thereby preventing the admission of atmospheric air. If the escape of gas is not sufficiently rapid, it may be easily increased by adding a little more sulphuric acid through the safety tube; the operation should proceed slowly and with all possible regularity.

If the gas contain arsenic, this will be deposited in the form of a ring, a little in advance of the heated part of the tube. The gas escaping through the capillary extremity of this same tube may be inflamed, and stains collected upon a porcelain saucer. In fact arsenical stains may always be obtained in this manner, when the heat is applied to a sufficiently extended part of the tube, or when this is not of too large a diameter. This tube may also be curved in such a manner as to admit of its being immersed into a neutral solution of nitrate of silver; thereby condensing the last portions of arsenic.

Metallic arsenic being once deposited in the tube, it is then easy to ascertain all the physical and chemical properties which belong to that substance.

1st. Its volatility.

2dly. Its transformation into a white sublimable powder (arsenious acid) when heated in a glass tube open at both ends and held in an inclined position.

3dly. By heating a little nitric acid, or eau regale in the tube, the arsenic will be converted into a compound very soluble in water (arsenic acid;) the solution evaporated to dryness in a small porcelain capsule will, by the addition of a few drops of a concentrated solution of nitrate of silver, produce a precipitate of a brick-red colour.

4thly. After being subjected to all these proofs, the metallic arsenic may again be isolated. To effect this, it is necessary to add a small quantity of black flux to the brick-red precipitate con-

tained in the capsule, and evaporate the mixture to dryness. This dry compound is then to be introduced into a glass tube closed at one end and drawn to a small orifice at the other. The mixture is then made to fall to the bottom of the broad extremity by gently shaking the tube, and is there subjected to a red heat.

The arsenic thus reduced to its metallic state becomes volatilized and condensed in the narrow orifice, forming a ring which presents all the physical properties of arsenic, even when there exists only a minute quantity of that substance.

It is easy to find in commerce, zinc and sulphuric acid not susceptible of yielding arsenic by Marsh's apparatus, even when a considerable quantity of zinc is dissolved. The sulphuric acid we made u e of, had been purified by distillation and the zinc was in very thin sheets.

In all cases it is absolutely that necessary the operator should carefully test all the substances he is likely to use in his researches; we even think preliminary experiments, or analysis, do not warrant a sufficient guarantee; but that it is necessary the operator should make blank experiments, immediately after his examination of the poisonous compound, making use of the same tests and in the same proportions as were used in the real operation.—Therefore if the substances have been carbonised by means of sulphuric and nitric acids it will be necessary to evaporate in a similar apparatus the same quantities of these acids as were used in the real operation; afterwards to add to the residue the same bulk of water; in fact to repeat with the tests only, all the operations he may have previously effected in the real examination.

7. The mode of carbonising animal substances by means of nitric acid, or nitrate of potash may be complete; but it sometimes happens one cannot prevent a violent deflagration, which often takes place towards the end of the operation, attended in all probability with the loss of a certain portion of the combined arsenic.

The carbonisation by sulphuric acid, and afterwards submitting the residue to the action of nitric acid, or eau régale, seems to us the most preferable method in many respects. The mode of proceeding given by Messrs. Danger and Flandin requires a much smaller quantity of reagent and the experiment is always without difficulty, when properly undertaken.

The results of our experiments lead us to conclude, that this mode of proceeding is attended with the loss of only a very minute portion of arsenic; one may prevent all chances of loss by carbonising the matter in a glass retort provided with its recipient.

8. It is of the highest importance that the carbonisation of the organic substance should be complete, without which not only is there obtained a liquor producing froth in the apparatus, but this liquor may produce stains presenting often a great resemblance to those of arsenic. The stains observed for the first time by M. Orfila and called by him "Taches de Casse" are often abundantly produced in cases when the organic matter has been imperfectly carbonised. These stains arising from the decomposition of carburetted gases are readily distinguished from those of arsenic by their chemical reaction; serious mistakes might, however, occur if the operator regarded only their physical characters.

9. All the experiments we have made to discover the arsenic which is said to exist in the human body in the normal state, have been attended with negative results.

10. The commission resuming the instructions contained in this report concur in the belief that for the wants of all medico-legal researches, the process by Marsh's apparatus, attended with all the precautions stated, will be quite satisfactory, especially as the quantity of arsenic to be brought in evidence is almost always superior to that which the sensibility of this apparatus can with certainty detect; it being understood at the same time, that this apparatus should be only used as a means of concentrating the metal, in order that its chemical characters may be studied with more certainty, and that the indication it might furnish should be considered of no value, or at least as very doubtful, in those cases where the deposit in the tube is not in sufficient quantity to admit of its being chemically examined.

We may add that in the greater number of cases of poisoning, the examination of the matter ejected, or of that which remains in the intestinal canal, will be sufficient to convince the operator of the presence of arsenic and that it will only be necessary to have recourse to the carbonisation of the organs when the first experiments have been unsuccessful, or in those cases (which are very rare) when presumed circumstances of poisoning seem to render it requisite.

Your commission, taking into consideration the importance of the question and the efforts which Messrs. Danger and Flandin have made to elucidate the use of Marsh's apparatus, beg to present them the united thanks of he academy.

Your commission think he academy is also indebted to Messrs. Lattaigne, Keppelin and Kampmann for their useful modifications in the mode of proceeding by Marsh's apparatus.

(To be continued.)

EXTRAORDINARY CASE OF ARTIFICIAL SOMNAMBULISM, AND CLAIRVOYANCE.

To the Editor of the 'Medical Times.'

SIR,—A few days since, I sent you an account of what passed the first time I mesmerised Calixte, whom, I then called "Caliste" by mistake. I am now going to give you an account of his subsequent sittings. During his second sitting, we were alone—I said I was ill, and begged him to examine me. He said, after feeling *himself* all over, that, "I had a pain in my head just there," (marking the spot exactly with his finger on his own head), "that the stomach was sore, and that I had a pain down the back, legs, and *knees particularly*." I asked which knee was the worst? "That," he replied, pointing to the right one; and continued, "the cause is irritation of the chest, for you have a cold, though you don't feel it yet." (For I denied the irritation of the chest, though he has since proved quite correct.) He promised me I should be quite well the next day, if I followed his prescription (which was very simple), but that I should have a little headache the next day, which would go off as the day wore on. The next day I was quite well, and free from pain, and the headache existed and went off, just as he had said; which, added to his discovering my painful knees, and that the right one was the worse, which no soul on this earth knew, was at least extraordinary. I then put him *en rapport* with a lady, whom I had often tried to put to sleep, but failed, and I asked him what I had better do to succeed. He just touched her fingers, and carrying his own to his nostrils, lips, and forehead, he seemed to reflect, then said with a start, as if frightened,—"She has already seen another somnambulist!" and then added, after a pause and a slight movement of surprise; "'tis Virginie! How I hate that girl!" and on my asking why—he said, "because she has ill-treated me, and was the cause of my leaving M. Ricard." How he arrived at his knowledge, unless there be a fluid, or some emanation, capable of passing from one body to another, is quite inconceivable. How could he tell which knee was the most affected! No soul in this world knew it but myself. He then examined for me, a sick person, whom, I know well, he had never seen; and, of whom, I have every reason to believe, he never heard of. He felt himself all over, and then described her complaint, and all her sensations most exactly; I then gave him some sealed letters to read, as I had done in his first sitting; but, as before, he said he could not, but promised to read them in a few more sittings, if I would always give him the same letter till he succeeded. Without giving him any notice, I then *mentally* desired him to get up and sit in a chair by his side, but a little further back. He seemed very much agitated, and desired to be awoke, but I did not comply, and still continued my will. He then got up, approached me, went back again, and I thought was going to take the chair I desired, but fell again into his former one; he pushed it back, however and made it occupy the space occupied by the chair I wished him to fill. I thought this pretty well for a first trial, and only the second time of mesmerising him. He asked me if I had not tried to awaken him by the "will" instead of by "passes," which he said I had not yet power over him sufficient to do; I told him I had not tried to do so, and then I awoke him.

Third sitting.—We were again alone; he said "he saw the sealed letter better than the last time—that he was sure he should read it; he could already, he said, see an 'm' and an 'it,' and show me which way the writing ran. He should first make out all the letters, and then arrange them in the order in which they are written." He never once has looked at the letters, but places them on his chest.

Fourth sitting.—About fifteen persons were present, some I dare say came with the idea of having a laugh at me; and, like all other sceptics, when called to see a mesmeric experiment, came very late; in consequence of which, experiments often fail. The instant Calixte was asleep, we proceeded to bandage his eyes with pads of cotton wool, and a white silk handkerchief. He played cards with the person who appeared the most sceptical in the room. It would not be easy to describe the surprise of the gentleman, who sat down to play with him when after he (Calixte) had sorted the cards, they cut for deal, and before he (Calixte's adversary), had himself time to perceive which had cut the highest, and with the cut cards still in his hand, Calixte moved the rest over to him, saying, "it is you to deal;" and on being asked to name the cards, he did so correctly. All the same experiments were gone through, as in the first sitting, of which I have already given you an account, and all perfectly succeeded. I showed him the sealed letter, and he then made out an 'E' and appeared very sure of reading it. We put him in a corner of the room, with his back to the piano, and begged him to beat the time to it, which he did, while a lady played; and, at a signal from one of the sceptics, I (standing in the middle of the room, between him and the piano), made him deaf, when he ceased to beat the time, and again began, when, on a signal, I made him hear. I proposed to try if he could receive from me a mental order, but stated, that I very much doubted, of any perfect success, as he told me he had not yet any community of thought with me, so as to answer mute questions. However we resolved to try, and one of the gentlemen wrote on a piece of paper, which was given me at the furthest end of the room from him,—"Let him walk up to you, and then pick up that handkerchief." I tore up the paper, and bid him mentally to do so. He got up, walked up to me, and there stood; he seemed very much agitated. He then had his back to the handkerchief, which lay at a lady's feet, and being close to her white dress, was not easily seen, even by a person awake and with his eyes open. He stood still for a moment and desired me to think well of what I wanted him to do. He suddenly gave a start, and with an exclamation, as if he had received an artificial shock, turned round and picked up the pocket handkerchief. I cannot conceive an experiment more fit to convince a sceptic. When we had concluded all the experiments mentioned in the first sitting, we proceeded to unbandage his eyes, which we had examined several times during the evening. I called the most sceptical round him, and made him put back his head till his face looked upwards. We then loosened the handkerchief, and turned up the cotton wool till we got to the eyes, when we found them quite embedded, open, and nothing but the whites to be seen. What could any one say? Nothing.—Those who had laughed at me and Colonel Murray, a few evenings before, as poor creatures easily imposed on, were mute, and confessed there was no room for deception; and, even if there were, there was no room to suspect any. Calixte was awakened at his own desire, and the Séance ended.

Fifth sitting.—We were alone; I desired Calixte to examine, a patient, who had been ill for a very considerable time, and who, I understand, has received no relief from the hands of the medical profession. I never saw her before, nor did I know her complaint. She was the *bonne* of a lady living over me. He described her sensations, pains,

complaint, &c., exactly; and described to me the state of all the vital organs. The poor woman was quite dumb-foundered at hearing her complaint described so minutely by such an utter stranger. He prescribed for her, and, to my mind, with the greatest good sense,—and things, too, which I should never have thought of.

Whether their power of curing equals their power of discovering the disease, I cannot yet tell; I must wait, before I can give an opinion, to see the effects of the several prescriptions he has given, and the result of his many promises of cures.

I have here, a female somnambulist, who is so excessively sensitive to the influence, that I am obliged to mesmerise her across the room, and very mildly (I mean with very little energy), or the blood rushes to her head and face, and she gets in a state not easily described; she talks, and will no doubt improve every day: she does not believe when awoke, that she has been asleep, but says, "she supposes she has, as her husband, and every one else tells her so; she also adds, "she does not believe much in mesmerism." It is surprising, Mr. Editor, that some of the medical gentlemen, who seem to feel with regard to mesmerism, as if it were a blister on their side, do not try to explain these, apparently to them, strange facts. Perhaps it may, in some way, be accounted for, by the impossibility of any one looking well into the subject, even with the intention of opposing it, without being himself converted. Vimont's collecting proofs against Gall, and converting himself, is perhaps an illustration of this: I cannot, but believe, that, at this moment, half the medical men in London, know the main facts of mesmerism to be true, but that each one fears to confess his belief, for fear of standing alone, the but of ridicule. Were mesmerism put to the ballot amongst the medical men of Paris and London, I think, if mean interest did not sway them to deny it, they would acknowledge such a state as *artificial somnambulism*, capable of being produced by one human being in another. I say "artificial somnambulism," for who does not know what there is in a name to prejudice mankind. The quantity of works published here on the subject of mesmerism [illegible] Editor, it is, to see [illegible] of [illegible] opposing it on the gr[illegible] its impossibility, while, to us, it is a[illegible] every day occurrence; and, we have, an[illegible] positive proof: yet these very men think [illegible] one for doubting any particular dogma of their particular religion, whatever religion that may be, though their facts are contradictory, and their evidence mere words and hearsay. Where is the consistency of such men? Could any man give me such proofs of the truth of the religion of the "fire worshippers" as I can give, and have received of mesmerism, before I believed one word of it, I would turn fire worshipper instanter. I fear anything I might say on the subject, Mr. Editor, might as well be left unsaid, for all the good it will do in advance of truth. If the evidence of such a man as Dr. Engledue, goes for nearly nought in the medical world, what weight can I hope to have! Still, frequent assertion of its truth, however humble an individual, may induce those who have not yet learnt to dispute the evidence of their senses, to look into the subject. Of course, from those to whom I am unknown, I have no right to expect much belief or credit; but, Mr. Editor, I do expect, and, I have a right to expect, that to those who have known me for years, and are well acquainted with my character, as one whose truth they cannot doubt, and at whose door, they have never yet had to lay the charge of [illegible], my evidence given in the simple way it is given, should be enough to make them think the matter, at least, worthy of serious attention. I do not say, it should make them believe, for I have formerly refused, and would refuse again, to accept what I now believe, on *[illegible] evidence*, as "not in proportion to the facts to be proved," which is the very nature and essence of [illegible] evidence. What a pity it is that most of the French authors mix up what they do NOT KNOW with what they DO KNOW, in the unreasonable way in which they mix up spirituality with mesmerism. They, by so doing, injure much their evidence; for while they rush into mad speculation, they get their facts suspected, by laying themselves open to the charge of being enthusiasts, and, doubtless, many of them are so.

I remain, sir,

Your obedient servant,

W. MACPHERSON ADAMS.

[illegible]

EXPERIMENTS IN MESMERISM.

To the Editor of the Medical Times.

On the 3rd instant, whilst waiting in Mr. Theakston's shop, a gentleman entered whom I had never seen before, and who proved to be Thomas Carstairs, Esq., surgeon, of Sheffield, visiting Scarborough to attend one of his patients. Mr. C. inquired for the *Edinburgh Review*, about which we began a conversation; took a glance at Christopher North, and ended about the last new discovery, mesmero-phrenology, when Mr. Carstairs declared he had mesmerised several persons both in Sheffield and Derby, where he had lectured on the subject. We expressed a wish to see some experiments, and he at once offered to shew the process if we would get him a subject. His deportment was open, candid, ingenuous and unpretending. There was not the slightest sign of any desire to astonish, or to make a marvel of the matter.

Mr. Theakston offered his errand boys for experiment, but Mr. C. failed of success in both cases, owing, it was said, to the noise going on in the printing-office, near the room where the experiments were tried. Mr. C., however, nothing daunted, said he would try again, if we would procure another subject. A servant of Mr. Leckenby's, on the opposite side of the street, consented to submit. She appeared a healthy, robust young woman of a sanguine bilious temperament, and about 20 years of age.

In the first experiment it seemed to require more time than subsequently to realize the coma or sleep, for she was three-quarters of an hour before she was put into the mesmeric state: Mr. C. during this time, simply looking or staring fixedly at her, and then making a few passes by the hand over the face, to close the eyelids. Whilst in this [illegible] Mr. [illegible] face, [illegible] producing the [illegible] of feeling or sensation; the face [illegible] remaining perfectly placid and serene, like one in a calm and dreamless sleep. In this condition she remained for about half an hour, during which time she was seen by several ladies and gentlemen, among others Mr. Dunn, surgeon, and Mr. Coulson, solicitor.

THE THIRD EXPERIMENT.—The same young woman again submitted herself to Mr. Carstairs, and as it appeared by the results, the party had become more susceptible to the mesmeriser's influence, for she was sent soundly asleep within eight minutes, and rendered apparently insensible to pain. Mr. C. was enabled to produce catalepsy of the arms, and to place them in an extended position, in which they remained until he altered the condition of the limbs. About 20 persons witnessed this experiment, and among the rest, that eminent physician, Dr. Simpson, of York.

THE LAST EXPERIMENTS. These were carried on at Mr. Dunn's surgery, and witnessed by a large party of ladies and gentlemen, amongst whom were J. E. Dennison, Esq., M.P., Major Thornton, Mr. Dunn, J. Woodall, Esq., Mons. Richard, and W. Bean, Esq. One of the subjects of experiment is a servant of Mrs. Barry, of Grove Villa, of a lymphobilious temperament. Mr. C. placed her in the chair, and taking her hands into his, he gazed at her for about ten minutes, when she fell into a profound sleep or the mesmeric condition, her eyelids closed, and the features wearing a placid expression. Mr. C. took his breast-pin into her hands and pricked her forehead and eyebrows, but she gave not the least indication of sensation or pain. He then raised her from the chair, and although still in the sleeping state, she stood alone, balanced and erect. Mr. C. then caused her to move a step or two, at the same time holding her by one arm, and then let her stand alone again for a moment. He next made a few movements before the body, without touching it, when to the surprise of every one present, the figure began to follow him with a slow and steady movement, gliding along like the ghost of Hamlet's father, dead to sense and feeling, yet alive and moving to the awe and wonder of the spectators. When he had retreated about three yards he stopped, the figure stood still also, when she had got close up to him, but without touching him. He then passed her on her right hand, when she slowly turned on her heels to the right also, and followed him back again, to where a chair was standing, on which Mr. C. next stood, and made several movements with his hands upwards above the young woman's head, but without touching it, when the body shortly began to give signs of making an effort to raise itself, and she stood on her toes. Mr. C. then placed her on a chair, and attempted what would have proved to me the most interesting feature in the experiment, namely the excitation of particular cerebral organs, but in this he failed, probably from the young woman not being put in the proper sleep—waking state. He succeeded, however, in getting her to speak, and to the question "Where are you?" she answered "at home." Mr. C.—"Are you comfortable?" Ans.—"Yes." Mr. C.—"What are you doing?" Ans.—"Sewing." Mr. C.—"Can you see anything?" Ans.—"Two candles." There were four on the table before her. A youth was placed before her at the distance of about 18 inches between her and the candles, and Mr. C. put the question "What do you see?" and she replied "A man." The writer stood about eight inches from the youth. Mr. C. then took his watch out of his pocket, and without speaking, placed his hand, holding the watch on the top of the head, over the organ of firmness and part of veneration. He then inquired if she saw anything? when she replied, "Yes." Mr. C.—"What?" Ans.—"A clock." Mr. C.—"What time is it?" Ans. "A quarter-past nine." The writer took Mr. C.'s watch from his hand and saw that the figures indicated the time mentioned precisely. Several gentlemen looked at their watches and declared that to be the exact time. This circumstance created considerable astonishment. That an individual apparently profoundly asleep, with the eyelids closed, could tell the time whilst the watch was kept at the back part of the top of the head was, indeed, truly surprising. One gentleman wished Mr. Carstairs to account for it, and he simply replied, "It may be a guess." Many, however, expressed their surprise that she should guess so accurately. Shortly after this the young woman was awakened by Mr. C. blowing in her face, or across her eyes.

Mr. C. then attempted to mesmerise three persons at one and the same time. The experiment was tried on the two young women above-mentioned, and one of Mr. Dunn's servants, who had also been previously mesmerised by Mr. C. The three sat side by side on the sofa, while Mr. C. sat opposite to them, and took the hands of two into each one of his own, and gazed fixedly at the centre one, and in about four minutes her eyes became fixed, glassy, and vacant. The one on his left hand fell into the same state in about another moment, and the third on his right in about three minutes after. He then put their arms into the cataleptic state, but in various positions: one with hands clasped and extended seemed supplicating; another, with the head a little averted and the hands held apart appeared to express disgust and abhorrence, whilst the third with her head more elevated and her hands apart and extended, seemed to express astonishment, mingled with admiration. The fixedness of their position suggested the idea of the mesmeric sleep being adopted for the study of the sculptor and the artist. When two of them were awakened they looked confused and surprised at the statue-like expression of their companion.

Mr. Carstairs stated in answer to some questions put to him as to the practical value of mesmerism, that he had extracted teeth from persons in the mesmeric state, and without any pain being inflicted on the patient; and also, that he had another patient who had been subject for 12 years to epileptic fits, and often had had two a day, and never went beyond two days without a recurrence of them, whilst for the last two months she had not had one owing to the application of mesmerism. Mr. Dennison informed the company in confirmation of

Mr. Carstair's statements, that on the Saturday previous, a person near Doncaster had had his leg amputated, without suffering pain. He had been mesmerised several times during the week previous to the operation by Mr. Topham, solicitor, and when the limb had been cut off and the patient was awakened, he felt grateful for having been saved from suffering, for the only circumstance that he could remember was hearing some noise like the "grunching" of a bone. It was also stated that when the limb requires dressing, he is thrown into the mesmeric state and the operation is performed without any suffering or annoyance to the patient.

Your Obedient Servant,

W. CRAIG.

Scarboro', Oct. 12, 1842.

[We must beg our correspondent to pardon our omission of his prefatory and closing remarks; we cannot give much space to mesmerism, and that little must be given to its absolute facts rather than its theories or reasonings. We have heard from another quarter of the amputation of a leg during mesmeric sleep, testified to by the Hon. M.P., and are not without hopes that we shall be able shortly to place all the circumstances of the astounding operation before our readers. In pursuing the course our readers have noticed in reference to mesmerism we have been guided by the opinion that the testimony of numerous, apparently, unimpeachable witnesses was so strong that if human testimony can evidence miracles, a position which no *christian* at least, and *we* think no *philosopher* can oppose, a fair case was established for ENQUIRY, especially as many of the wonders artificially produced, or rather invited out by mesmerists have, as is well known to every medical reader, presented themselves naturally in the swoons, catalepsy, transposition of senses and double consciousness of several well attested cases. The alleged facts of animal magnetism are, if true, the most deeply interesting that can occupy the attention of the human mind; and are pregnant with services for science and for mankind which the most enthusiastic imagination would probably find it difficult to overrate. If the facts are suppositious we are anxious, that our profession may have the honour of discharging one of its first duties, permanently undeceiving the public on an important point of medical science; if on the other hand the facts are true, we are anxious that our profession may have the high and appropriate distinction of early recognizing and honestly establishing them in the credence and esteem of society. We cannot—we consider—be too cautious in dogmatically laying down our own imperfect and limited notions of possibility as the unchangeable law of mystic and unfathomable nature's doings, and as medical men who have characters at stake, and who cannot be proved fools by the future except with some loss both in cash and reputation, we have perhaps no better piece of property than *a reasonable doubt*, and no higher wisdom than the wisdom of not being overwise.—ED.]

EPIDEMIC ERYSIPELAS,

Affecting the Throat, Face, &c. &c.

By J. B. Johnston, M.D.

(For the 'Medical Times.')

THE months of January and February of the winter of 1842, in Eastern Canada, which are usually the coldest and most severe, proved to be singularly mild, though the weather was exceedingly changeable, alternating frequently from 5 deg. below zero one day, to a complete thaw on the next, with a warm rain or bright sunshine. The consequence of such very unseasonable weather, was a most unhealthy state of the atmosphere, engendering every species of sore throat, quinsy, mumps, &c. Scarlatina likewise prevailed to some extent in the beginning of winter. But the most serious disease that arose about this time, was a singular species of erysipelas, attacking, in the first place, the throat and fauces. The tonsils, velum palati, and pharynx, exhibited a deep erythematic redness, followed, soon after, by great puffy swelling, attended with heat and burning pain of those parts, great difficulty of deglutition, food and drink being often returned by the nose; in some cases, so great was the swelling inside the throat, that if free incisions had not been made in the tonsils and neighbouring parts, suffocation appeared likely to ensue. The parotid and other glands about the neck, were much enlarged and painful; indeed, the first symptoms were generally pain and stiffness under the ears, followed by rigors, nausea, headache, quick pulse, thirst, and all the attendants of fever, with sore throat. After the affection of the fauces had continued two or three days, sometimes sooner, if not arrested there, erysipelas shewed itself in its true character on the face and head; where it would appear to have propagated itself by continuity of surface, for, after considerable pain and itchiness inside the nose, an erysipelatous spot would appear on the nose, whence it gradually spread in all directions, until the whole head and face were involved, producing the usual disfigurement of the features. The ears, more particularly, suffered from swelling and a deep-seated pain, which was in most cases followed, after some days, by a discharge of muco-purulent, or sanguinolent matter, from the meatus externus. Large vesicles, filled with serum, formed on the cheeks, forehead, and ears. The affection of the throat generally abated when the disease appeared on the face; desquamation of the cuticle took place, as in ordinary erysipelas, and an analogous process occurred in the mouth and fauces. Delirium was a very constant attendant on most cases. In some instances the complaint was confined to the throat alone. In the progress of the epidemic the disease changed its character in some respects, being accompanied with less debility than at its commencement. A peculiarity attending it was, the discharge of purulent or muco-purulent matter from some outlet, generally from the ear, sometimes from the nose, indicated by great pain over the frontal sinus. In other instances, large quantities of muco-purulent matter were expectorated for several days, without apparently any previously-existing disease of the chest. In the greater number of cases, large abscesses would form in different parts, but principally about the scalp, neck, axilla, or on some part of the thorax: these accumulations of matter invariably marked the decline of the disease. They took place in situations where there had not been any erysipelas, as well as on those parts that had been affected. It was remarkable, also, that at this time a great number of persons were subject to the formation of abscesses in different parts of the body, particularly about the glands of the axilla and groin, who did not labour under any local sore, and who had no other complaint; others, again, had very considerable febrile symptoms, with severe local pain, which would yield on the appearance of a collection of matter, containing sometimes from one to two pints of pus. Many persons, also, who were not attacked with any of the more marked erysipelatous symptoms, complained at this period of great lassitude, debility, and drowsiness, with slight sore throat; being evidently minor symptoms caused by the same epidemic. Sometimes the erysipelas of this epidemic appeared on the extremities alone, or on some part of the trunk of the body; in these situations, if not speedily arrested, it would shortly over-run the whole body. The pain and tenderness of the parts affected, appeared excessive. The persons most attacked by the disease, were (contrary to what obtains in ordinary erysipelas) children under puberty, and females, especially those in a state of pregnancy, who generally miscarried in consequence. In many instances, it appeared to be contagious. The convalescence was for the most part tedious, great debility being left behind, requiring the free use of wine and tonics. The bowels were often remarkably obstinate, rendering the use of croton oil necessary; the stools, in such cases, were of a pitchy blackness, with pain on pressing the region of the liver. In some cases, the disease spread down the pharynx, causing very urgent symptoms, mostly from the secretion of a viscid phlegm, clogging up the passage already much contracted from the swelling, and a feeling of burning pain extending down the œsophagus. In one instance I witnessed, the larynx appeared to be the principal seat of the complaint, giving rise to all the symptoms of cynanche laryngea—the patient recovered: in the same family, there were several cases of the disease, shewing itself in the face and throat. Sometimes it appeared to develope itself in the stomach and bowels, producing incessant retching, vomiting, obstinate costiveness, discharge of flatus, with great pain and heat of those parts. In Vol. II., p. 128, and Vol. III., p. 91, of the Transactions of the Medico-Chirurgical Society of Edinburgh, is recorded an account of an "Epidemic and Contagious Erysipelas, accompanied by a severe affection of the throat and larynx, which prevailed at Montrose, in Scotland, in 1822;" which appears to have resembled the one which I describe as prevailing in this part of Canada this year. In this town, containing a population of about a thousand inhabitants, nearly one-half were affected in some degree by the epidemic. The mortality, except with young children, was not very great, where proper medical assistance was had; left to itself, the complaint was very dangerous, from its propensity to spread and involve important organs. It has now continued for upwards of six months in this part of the country, but is evidently on the decline. It appears to prevail mostly in small country parishes, avoiding large towns. The country around is elevated and dry, and esteemed very salubrious. In 1832 and 1834, it was one of the few places in Canada not visited by Asiatic cholera. However, this year, the interments in Sherbrooke have more than tripled the average number of previous years. I may mention, in connection with this epidemic, that a very fatal distemper prevailed among horses, this last winter, in all the places where erysipelas shewed itself, which was characterized by many of the symptoms of that complaint, particularly about the throat. It was also observed that, for some time previous to the appearance of the epidemic erysipelas, slight cuts or scratches did not evince any disposition to heal, but would become inflamed and painful, and that punctures and wounds were frequently followed by severe diffuse cellular inflammation.

The treatment pursued in this epidemic was conducted on general principles. Blisters, in the early stage, were of great benefit, applied to the neck or behind the ears; they always relieved the swelling inside the throat, and required to be frequently repeated, or kept open. After a few days, stimulating poultices were put over the ears, to encourage the discharge from them, which frequently carried off the complaint. The head was generally shaved, and bladders of ice applied to it, with relief to all the symptoms, particularly the delirium. The bowels were kept open, principally by Croton oil, astringent gargles made use of, and when the fauces were much swollen, incisions were made in the tonsils and uvula. It was found very difficult to produce any action on the skin, the function of which appeared to be discharged by the kidneys, the secretion of urine being most copious throughout the disease. Whenever the erysipelas shewed a disposition to spread on the surface of the body, a very strong solution of nitrate of silver was applied, and if this did not succeed in arresting it, I generally touched the erysipelatous margin with the solid caustic, frequently to the extent of producing a blister, which almost always put a stop to its further progress. Some anodyne was generally necessary—belladonna and hyoscyamus appeared to answer best. Whenever any part evinced a tendency to suppuration, this was encouraged by poultices and fomentations. Bleeding from the system did not appear necessary, more particularly as all the diseases of the period were marked by debility; but blood was frequently abstracted locally from the head, temples, and throat, with decided advantage; leech-bites did not take on any bad action.

In the large towns, puerperal fever prevailed at this time, epidemically, yet no case came under my notice, of puerperal fever supervening on such women as miscarried while labouring under erysipelas. It was considered hazardous to vaccinate children during the epidemic under consideration, some having been reported to have died from erysipelas supervening after the inoculation.

I have made these remarks on the epidemic erysipelas, as it appeared in Canada East, in 1842, but as it likewise prevailed extensively at the same

time (and, I believe, still continues) in the neighbouring States of America, I hope shortly to see a better and more extended account of it in some of the medical periodicals of that country.

JAMES B. JOHNSTON, M.D.

SHERBROOKE, Canada East, Aug. 5, 1842.

ON THE SECALE CORNUTUM.

(In Answer to J. RIDOUT, Esq., Stratford, E. . . .)

SIR,—I am, at all times, most willing to give every information in my power, particularly on those subjects which I have communicated to the public. In respect to the matter of enquiry, viz.—"*In every respect do I agree with you, as to the priority, the decoction of Ergot of Rye claims over every other preparation of that drug; but there are to be met with many cases, where the secale cornutum is especially indicated, and where the delay in its administration, occasioned by the necessity for its extemporaneous decoction, would be attended with dangerous and not unfrequently fatal results. If you could point out any way, in which this evil might be obviated, it would, doubtless, be read with great eagerness and attention, by many others, as well as yours, &c.*

In answer to this, I beg to observe, my long and most extensive experience of the Secale Cornutum, enables me to meet the question without any difficulty. I acknowledge, that it is possible, that circumstances might occur, when a few minutes are of the greatest consequence, both to the patient and practitioner: but I have never yet met with a case (and on referring to my papers, my opportunities have not been few), when the time in preparing, and exhibiting the decoction, could have been said to have been time lost. The plan I adopted (when in active practice as an accoucheur), was simply the one I would earnestly recommend to others: which was this, I kept the Secale Cornutum, finely pulverized in doses of ℈iv. to ʒij. wrapt in pieces of sheet lead, obtained from the inside of tea chests, which enables the secale to retain its qualities unimpaired for a considerable time without occupying much room in my waiscoat pocket. In any case of emergency (such as you have so properly suggested), I called for a small saucepan, and a tea-cup full of hot water, if any at hand; if not, cold: and boiled it quickly. In five minutes I poured half the decoction off into a vessel for immediate use, and allowed the rest to digest a few minutes longer till wanted, giving each dose as hot as it could be conveniently taken. In my paper, on this subject, I allow a longer time for making the decoction which ought to be followed if time will permit: but if the secale be sufficiently powdered, its principles as a stimulant, are soon given out to the water; and if the case be really urgent, the above plan may be acted upon with advantage. From what I have observed of this valuable medicine, I feel certain, the action of the decoction is both quicker, and more effective than the powder given in substance; so that the time lost (or supposed to be lost), in preparation, is positively (when compared with the action of the powder), no loss at all; indeed, I question, if it be not a gain of time, rather than otherwise. I have often had to wait for a considerable space for the action of the powder; on the contrary, if the rules I laid down in my essay, be properly attended to, I have always found the action of the decoction to be almost immediate.

Hoping the above will be a sufficient explanation, and thanking you for your candour in making the enquiry,

I remain, Sir,
Your's respectfully,
CHARLES CLAY, M.D.

3, Piccadilly, Manchester.

Count Jaubert, known in the world of letters, by his botanical works, is at present preparing for publication, the travels of Aucher Eloy, a young French botanist, who, after struggling for ten years against a variety of dangers in visiting Egypt, Arabia, Syria, Cyprus, Greece, the Islands of the Archipelago, and Persia, lately expired at Dejulfa, near Ispahan.

SUSSEX COUNTY HOSPITAL. A vacancy has occurred in the surgeonship of this institution, by the resignation of Mr. Whitehouse.

TO CORRESPONDENTS.

College of Surgeons.—*We have received a great number of letters on the new regulations of the College of Surgeons. It is complained with great justice that their retrospective operation is a cruel injury to numerous persons, whose fortunes are more or less embarked in their son's receiving a diploma at the time, which, on entry, the College regulations gave him assurance of, provided he should be able satisfactorily to prove his competency. It is easy to conceive that the means of many a family may extend no further than the payment of the expenses required by the less exacting rules, and that if the College had required at the entry of a young man its present more costly course, they would have shrunk from the undertaking as beyond their means. There was here then a moral contract with the students which should not have been broken. We cannot too earnestly impress on the Council the necessity of immediately amending their oversight. We are aware that the Council are making many exceptions in the operation of their rule—why not at once do what justice, humanity, and wise policy require, exempt publicly from its operation all students entered before its emission?*

A Surgeon and Subscriber.—*No Surgeon can foist an empiric into a Poor Law Medical Charge under the pretence of partnership. Let the circumstance be mentioned to the Poor Law Commissioners if the Guardians connive at the wrong.*

F. *On the Proposal for forming a Sydenham Publishing Society, next week—as also Cases by Mr. Thornton, Mr. G. Laing, Mr. Annan, &c.*

A number of Correspondents under consideration.

Dr. Sufferen's Lecture on Chemistry—Mr. Nettingham's on Operative Surgery—M. Serres on the Development of Organs, Dr. Williams on Medicine, in our next.

We are obliged to postpone our concluding notice of Sir A. Crichton's Book till next week, as also notice of one or two other works.

Mr. Johnston's Case of Tetanus, cured by large doses of opium, and Dr. Gore's Communication on a New Preparation of Secale Cornutum, have been received.

Vols. 1, 3, 4, 5, *are ready in boards, price* 7s. 6d. *Vol.* 6 *is also ready, price* 10s. 6d.—*N.B. Vols.* 5 *and* 6 *were published under present management. Double price will be given for copies of No.* 34.

NOTICE.

ON THE 1ST OF DECEMBER NEXT, WE PROPOSE TO PUBLISH, AS AN APPENDIX TO OUR ORDINARY NUMBER, A *Medical Almanac*, FORMED ON THE ADMIRABLE PLAN FOLLOWED BY MESSRS. FOOTE & FARRE, IN THEIR ANNUAL POCKET BOOKS, AND REPLETE WITH MATTER THE MOST VALUABLE AND INTERESTING FOR THE MEDICAL PROFESSION. THE ALMANAC WILL CONSIST OF 72 QUARTO COLUMNS, AND WILL BE SOLD AT THE ORDINARY PRICE OF OUR JOURNAL VIZ. 4D. PLAIN, 5D. STAMPED.

THE MEDICAL TIMES.

SATURDAY, OCTOBER 29, 1842.

"Divide et impera."

WE have heard a great deal of nonsense, of late, on the Division of Labour. A certain Dr. Robert Hull whom, from his recent rather protracted silence, we may congratulate—we suppose—as in the enjoyment of a lucid interval, has been venting on this *interesting* subject we know not how many rhapsodies, in which, if his over-larding quotations were a little less infelicitous, or shewed the least imaginable connection with the topics he evidently wishes to write on, we should be led to consider his ignorance of the vernacular atoned for by some knowledge of the Greek—as his lack of sensible *ideas*, is fully explained by his marvellous plenitude of silly, pedantic *words*. As might have been expected, his notions have found much favour with a contemporary, who, to speak charitably of him, appears never to have written a line for his readers which was not penned under an impression, that to set his brain a-working would be a mortal sin against his one virtue—gentility; we mean, of course, the Editor of the *Medical Gazette*. This rational gentleman, backed by all the powers of Hull, has even taken the trouble to elaborate a leading article, demonstrating first, the utilities of a division of labour (a startling novelty in the way of proof, which would make the loss of Adam Smith's works a mere bagatelle); secondly, the advantages of a division of study and practice of different medical men, on different medical subjects, (a momentous matter never disputed, we may say, for the repose of mind of Dr. Hull and our genteel contemporary); and, thirdly—as a logical corollary—the benefits of two Colleges, *one* for Surgery, the *other* for Medicine—and *both* for jobbing, intriguing, and nepotizing. Our readers will pardon our insinuating that our two *genteel* friends were paying a sneaking thought to the last items of *their* tripartite division of labour; it is a compliment we are paying their judgments, for humbly as we may think of the men, we cannot suppose that such an intemperence of nonsense as they have indulged in, had no *human* temptation for its excuse, and, save fatuity, no *earthly* motive for its origin!

The first piece of absurdity of your men of division is—as we have already hinted—their inference that because the special study of special diseases has its advantages, therefore, a demarcation should be made, which confessedly has reference, not to the specific character of the diseases, but to that of their treatment,—a demarcation, the location on either side of which is decided, not by the nature of a man's study, or knowledge of this or that class of diseases, but by circumstances which have little or no connection with either. Let us concede that every disease shall have its own doctor—and the utmost rage for division can surely ask for nothing more than this—why shall surgery and medicine be separated, and confided to two classes of doctors? The two kinds of divisions have no relationship. They are not idem generis. They, in truth, exclude each other. The doctor of one disease, must be at once surgeon and physician, or else, he is but half master of his specialty: and the surgeon or physician, who carries out the principle of division of labour to its due limit, viz., taking one disease under his charge, has, in doing so, ceased to be surgeon or physician—he is both. So that in truth, the very principle of division of labour—so foolishly lauded by our elaborately empty Hull—and our weekly register of wit's bankrupts—the *Gazette*—is the very principle which proclaims the absurdity of the division into Surgeons and Physicians. The greater, coarser, section cannot coexist with the perfect and more refined demarcation. But let us suppose

that these two divisions can coexist without crossing each other, how absurd still is the course of deducing, from the advantages of *several* separate practices, the usefulness of having *two* separate Colleges. If the principle be, that specialties in practice shall be represented by specialties in Colleges, why shall not Mr. Curtis, and that modest *protegé* of the *Dispatch*, Mr. Yearsley, preside over a Corporation of Aurists? Why should not Dr. Monroe and Dr. Sutherland form the Council of a College of mad doctors (to which, by the way, Dr. Hull would form an essential attaché)? Why, in short, should there not be as many Colleges as there are peculiar branches of practice? If we are told that two governing bodies may *properly* take them all into their dual jurisdiction, we deny the statement. Our contemporary, singularly enough, cites Dr. Prout's case as evidencing the advantages of the present system. Now, which College, we ask, can *properly* claim him? *Both* cannot—for membership in one, *enforces* non-membership in the other. *One* cannot—for his practice is essentially *dual*. But even if two Colleges *could* include all practitioners, why might not *one?* A man may doubt whether his practice be surgical or medical—but no one of us doubts his being a member of the medical profession. Whatever two Colleges can do for us separately, could be done quite as well by them in a state of incorporation, with a saving of much time, much money, much order, much personal warfare, much general discontent.

But we are told:—"The divisions in the practice of medicine, give an opportunity to the lovers of *its science* to pursue whatever branch their fancy or interest dictates. They may choose the arduous but more profitable life of the general practitioner; they may engage in the learned studies of the physician, or they may give scope to their dexterity as pure surgeons!"

The scholastic essayist (who talks of medicine's science, and of dictating a branch!) is evidently as much at sea in his notions as in his verbiage. He labours under a double hallucination. He obviously fancies that medical reformers object to divisions *in practice*, and thinks that, because men should study that part of medicine which pleases or interests them most, they must, of necessity, have specifically *three* governing corporations! How astounded would our contemporary probably be, if told that, incorporated into one Faculty, "the lovers of medicine's science may yet," in the words of his own theme, "choose the arduous but more profitable life of the general practitioner; they may engage in the learned studies of the physician, or they may give scope to their dexterity as pure surgeons!"

In very truth we know of no more preposterous thing than the notion of separating surgery and medicine. It is about as wise as the divorce of anatomy and physiology. Essentially knit together by nature, we may abstractedly *imagine* a distinction in thought, but no ingenuity can enable us to maintain it in practice. We have only to consider for a moment the rapid uprise in respectability and pretensions, of the body of general practitioners—the variety of *mints* in which medical men receive their moulding, superscription, and title—the difference of qualifications or stations indicated in different places by the same names—and the vagueness and confusion of titles and practices which thence originate,—a result which, though springing from different sources, is observable in the practice of our most noted surgeons and physicians,—we have only to reflect on all these positive facts, to feel the absurdity of all our opponents' pretty speculations, and the madness of endeavouring to maintain a barrier of division which exists neither in nature, reason, nor expediency,—and which, without penal enactments in its favour, can not possibly support itself for another twenty years!

The last Regulations of the Poor-Law Commissioners, demanding, among other requisites, membership of a British College of Surgeons in all Poor-Law medical officers, are fresh in our readers' remembrance,—and they probably recollect that, impressed with the hardship which the requisition of a double diploma would entail on hundreds of gentlemen, who, from their possession of the Hall's License, were held competent by law to act as medical practitioners, we strongly represented to the College of Surgeons the expediency of admitting such sufferers to membership, under reduced fees, and with a suspension of the customary regulations. We are told that the Council, entertaining our proposition, under the presidentship of Mr. Guthrie, came to a resolution, which—though not conceding all we suggested—yet conceded enough to make their offer a boon of no small importance to a great many country practitioners. For some reason we are not acquainted with, this decision was not, at the time, officially made matter of publicity: to thousands, our last number was the first intimation that such a step had at all been taken. Yet we are told that, as early as July last, a letter was sent by Mr. Guthrie to one of the most influential public officers of the Provincial Medical and Surgical Association, announcing the circumstance, and begging that it might be made known to the members at the then approaching annual meeting. The letter ran much in this form:—

1, Berkeley Street, Berkeley Square,
July 14th, 1842.

Dear Sir,—I send you herewith a copy of a letter I have addressed to Mr. Howell, the Senior Member of the Surgeons of the London Unions, on the subject of the augmentation about to be made by Government to the sum already paid for the medical relief of the poor, which I shall be obliged by you making known to the gentlemen composing the Provincial Medical Association.

I regret very much that circumstances should render it necessary for the older members of the profession, who have no qualification, to obtain that of the College of Surgeons of London, in addition to one in Physic and Pharmacy.

The difficulty they might suffer from, has been, however, removed by the kindness of the Court of Examiners, who have, and are admitting, gentlemen of their standing to examination, on their merits practically, without reference to the regulations which are in force as to their education. There is no difficulty then in obtaining the diploma, except in the want of capability, which I trust will not be found among the gentlemen to whom I have alluded; and the expense to which they will be subjected, must be as nothing compared with the advantages which will be derived from the qualification.

I am, Dear Sir,
Your faithful Servant,
(Signed) G. J. Guthrie.

To Dr. Hastings, Worcester.

Will Dr. Hastings oblige us by answering three questions on this matter? Did he receive such a letter? If so, did he announce it to the members? If not, why did he decline? We infer not—we cannot *yet* infer—any charge against Dr. Hastings, but an answer to these queries will obviously be as much required by his reputation as expected by provincial practitioners.

LECTURES ON THE ANATOMY AND PHYSIOLOGY OF THE NERVOUS SYSTEM.

By Professor OWEN, F.R.S., &c.

The brain of birds, like that of reptiles, consists outwardly of five principal masses, namely, the two hemispheres of the cerebrum, the two optic lobes, and the cerebellum, to which ought perhaps to be added the cerebral expansion of the spinal chord, called the medulla oblongata. This, however, as in reptiles and fishes, is without that inferior superadded body, called the pons varolii, or nodus encephali in mammalia: only an obscure representation of it, consisting of a thin layer of arched transverse fibres, the lower ones answering to the areiform filaments, can be discerned with any distinction in the largest birds, as the ostrich. The cerebellum offers in all those oviparous vertebrata, which can sustain themselves in the atmospheric ocean, the same complicated transversely folded condition as that which characterizes the strongest swimming fishes that soar in the upper regions of their atmosphere of waters; birds in this respect manifesting a sudden resumption of a type to which none of the grovelling reptiles could ascend. The optic lobes, by reason of the superior development of the cerebellum and cerebrum, occupy a different position to that which they heretofore presented. Instead of one line or series of tubercles, they are now pushed down below the level of the larger and cephalic masses, and are lodged in the inferior and lateral interspace of the cerebrum and cerebellum.

The accurate anatomist Coiter, was the first to notice, in 1573, the characteristic differences which the brain of birds presented as compared with that of quadrupeds in the absence of convolutions in the cerebrum, and the presence of an unusually large pars vermiformis in the cerebellum. Willis, extending his comparisons to the internal structure of the brain of birds, detected the absence of the corpus callosum, the fornix, and, as he believed, also of the corpus striatum; he describes the anterior and posterior commissures. Haller regarded the two small grey tubercles upon the crura cerebri anterior to the optic lobes, as the corpora striata. Soemmering and the Wenzals called the bigeminal bodies or optic lobes the thalami. Cuvier also considered the optic lobes as the optic thalami, and describes their true analogues as small appendages of the crura cerebri; they are, in fact, present in all birds, and form the lateral walls of the third ventricle. Cuvier, however, rightly considers the hemispheres as being formed almost exclusively by the corpus striatum. Malacarne held the anterior commissure to be the corpus callosum. Tieddeman denies this, and points out the commissure of the optic lobes, the pineal gland, and the sylvian fissure more accurately

than his predecessors. Meckel and Carus admit a rudiment or germ of the corpus callosum, and describe the ganglions at the origin of the acoustic nerves.

The cerebellum of birds consists almost exclusively, of the parts corresponding with the superior and inferior vermiform processes, as in the mammalian brain. The inferior process is, however, always smooth and without transverse plications; the superior is deeply folded, but with so much regularity, as to permit the plications being counted. It is important to observe, that the number of these folds which give the essential degree of complication to the cerebellum is directly as the swiftness and vigour of locomotion, inversely as the duration and physical pleasure of the coitus. Thus, in the drake or gander, which are provided with an elongated spiral, and largely developed intromittent organ, the number of folds in the cerebellum is thirteen or fourteen. In the sparrow, there are seventeen; in the jay, eighteen; in the magpie, twenty; in the swift, twenty-five. In none of these passerine birds, does an intromittent organ exist. Indeed, in no birds, save certain aquatic species, where the union of the sexes takes place on the water, is there any intromittent organ. They are, in this respect, worse off than the crocodile, the tortoise, the lizard, or the snake, in which the cerebellum is smooth, simple, and of much smaller proportions.

The cerebellum in birds, consists of a double plicated layer of nervous matter; the outer one grey, the inner one white, having an ample cavity in the centre, continued from the fourth ventricle. It is connected anteriorly by the valvula Vieussenii, —which is the most central and general, and apparently most important of all the commissural apparatuses of the brain—with the optic lobes, and the crura cerebri. It is connected laterally, as you perceive, in this preparation of the ostrich's brain by transverse fibres, forming a kind of diffused commissure with the medulla oblongata. It is connected behind, with the posterior and lateral columns of the spinal chord. The fourth ventricle is a deeper excavation than usual, and presents the median-longitudinal division or calamus, and the acoustic tubercle. The optic lobes form a single pair of hemispherical bodies, which we have seen to be regarded by some anatomists as the thalami optici, and by others, from their inferior position, have been called corpora mammilaria. Their order of development however, the analogies of the permanent embryo-like forms of vertebrata, and the transitory embryonic stages in higher animals, prove them to be the optic lobes, the analogues unequivocally of the bigeminal, or part of the bigeminal bodies, in the mammiferous class. This latter question is one of much interest, and which besets us in the first comparative glance, which we take of the brains of birds and mammals. Are the single pair of optic lobes in birds, which give exclusively origin—a double origin—to the optic nerves, are they the analogues of, or do they represent the whole mass called bigeminal bodies in mammalia? Are the bigeminal bodies in this class, the result of the superaddition of a transverse to the longitudinal cleft, which alone divides them in birds? Or, are the optic lobes in birds, the analogies of only one of the pairs of the bigeminal bodies in mammalia? And if of one only, of which? Some years ago, I sought in the works of the authors on Comparative Anatomy, for a satisfactory solution of these queries and in vain. I am not aware that the question is decided by sufficient inductive enquiry or analogies in any work. You will observe, that the optic lobes in birds, are far apart united by a broad thin medullary plate, covering a broad channel of communication between the third and fourth ventricles; you will observe, that the valvula Vieussenii, which connects the optic lobes with the cerebellum, is likewise of usual breadth, and that that part which is immediately posterior to the optic lobes forming the anterior terminations of what would be called, processus à cerebello ad testes, is somewhat thicker than the rest. In the brain of the ornithorincus, and of the echidna the optic lobes are again approximated towards the median plain, and the anterior part of the valvula and processus à cerebello, which are connected with them, present a still more marked enlargement, but do not yet project as a distinct pair of lower yet broader tubercular masses. This is the form, however, which the posterior bigeminal bodies or testes, as they are termed, present in the marsupialia and rodentia. By this series of analogies, we clearly perceive that the testes consist of a distinct and special development of cerebral matter in a part analogous to the broad and thin plate behind the optic lobes in birds; and that these lobes, therefore, are strictly, the analogues of only the nates or anterior pair of bigeminal bodies in the mammiferous class. The anterior and largest encephalic masses, called cerebarl hemispheres, are remarkable for their pedunculated connection with the rest of the brain. They present a slight oblique depression at their base, representing the fissura sylvii, and in a few of the more intelligent birds, as the magpie and parrot, there is a small longitudinal fissure at the upper and fore-part of each hemisphere. They present no other traces of anfractuosity or plications in any other part of their surface. The median side of the hemispheres, which are in contact are smooth and flat, and this contact is seen to be converted into union of substance at only one very small part at the bottom of the fissure by the chord analogous to the anterior commissure in man. A very remarkable series of radiated white fibres diverge from the anterior part of this commissure upon the flat, median surface of the hemispheres. The rest of the cerebrum consists of a reddish grey substance, traversed by very numerous white striæ which radiate from the crura. There is no distinct layer of grey and white substance, no cineritious cortex, this exists only in the cerebellum. There is generally a small pyriform olfactory tube at the anterior apex of each hemisphere.

The brain in birds, as in reptiles, bears a proportion rather to the heart than to the whole body. In the humming bird it is as one to twelve; in the ostrich as one to three thousand; the median, or average proportions of the brain to the body of birds, is computed by M. Leuret to be one to two hundred and twelve. The breadth of the brain always exceeds its length. The hemispheres chiefly consist, as Cuvier has stated, of a mass of cerebral matter, which, by its intermixture of grey and white matter, resembles the corpus striatum. The cerebrum has been thought, from its large proportionate size in some of the lightest and most diminutive of the feathered tribe, to be better developed in them than in the elephant, the orang, or even in man himself. But the supraventricular mass of cerebral matter, which constitutes the actual characteristic superiority of cerebral organization in the brain of mammalia, is in birds not better developed than in reptiles. The lateral ventricles—the only cavities in the cerebral hemispheres—are covered laterally, superiorly, posteriorly, by the thinnest imaginable fibre of medullary matter. Space seems to be almost altogether denied for the location of the phrenological organs, to which the very striking and various physchological manifestations, and instincts of the bird might be assigned. The corpus striatum here monopolises almost the whole of the cerebral division of the brain. Even that posterior boundary or wall of the ventricles, in which the instinctive cares and affections for offspring have been conjectured especially to reside, presents no appreciable increase of development in the nest-building, fond, feathered mother, who not only toils daily to feed, but broods over, cherishes, protects, and even fights for her offspring. The so-denominated organ of philo-progenitiveness has no greater development in bird than in the crocodile, which manifests its instincts and feelings towards its offspring by devouring them.

CASE OF GUN-SHOT WOUND.

By W. CRUIKSHANK, [illegible]

(For the "Medical Times.")

Mr. I. R. J., æt. 28, of sound constitution and perfect health, was returning from a shooting excursion, in the month of December, 1840, with his fowlingpiece loaded in the usual manner, with powder and small shot. On casually placing his right hand upon the muzzle, from some opposing substance coming in contact with the trigger, the powder was ignited and the contents discharged, producing a dreadfully lacerated and contused wound of the radial side of the metacarpal portion of the hand; the wound presented such appearances as are observed on discharge of fire-arms so close to the injured part a large, black, and ragged aperture. The metacarpal bone of the fore-finger was battered to pieces, as well as the os trapezium, to which it is attached at its carpal extremity. Mr. Cruikshank, on being immediately called to the case, found the fore-finger hanging by its flexor tendon, which he immediately cut across. He forthwith procured the assistance of two of his professional brethren, and commenced dissecting out that portion of the shattered metacarpal bone which remained, as also the fragments of the os trapezium: which dissection was effected with some difficulty, on account of the bones fractured with so much violence, having their fragments irregularly imbedded in the surrounding soft parts. The injury thus involving the synovial capsule of the wrist joint, rendered the case of the most serious nature; but Mr. Cruikshank resolved, along with his professional brethren, to save the hand, trusting to treatment, and the advantages of a good constitution to effect the cure.

A common bread and water poultice was applied for the first week, during which period, an abscess formed on the ulnar side of the wrist joint. The abscess was opened and the treatment changed for cold applications, in the form of keeping cold water constantly dropping upon the injured parts. This had the effect of removing the inflammation considerably; but in order to do so still more effectually, leeches were applied at intervals, during the process of the cure. The regimen of the patient was strictly antiphlogistic; consisting of occasional purgations, nauseants, low diet of a vegetable nature, and cooling diluents. This treatment was persevered in for the period of two months; at the end of which time, the wound was nearly healed, when the local applications were changed for that of simple dressing; which forming the final treatment, was continued till the wound was perfectly closed.

Afterwards the use of the fingers was gradually recovered by gentle exercise and friction with the linimentum camphoratum; but the wrist joint remains completely anchylosed.

EXTRACTS FROM FOREIGN JOURNALS.

ON WOUNDS OF THE HEART.

(Translated from the [illegible] Zeit[illegible], for the "Medical Times.")

([illegible] Vol. VI.)

We may put forth the following propositions for judging the danger and fatality of heart-wounds.

1st. All penetrating wounds of the heart, from which death suddenly follows, are to be pronounced fatal, whether death be caused by hæmorrhage, or from pressure upon the lungs and heart, or, in fine, from the nervous system by spasm and paralysis of the heart. We would call it hæmorrhagic death, when the patient has lost much blood externally, when one-half of the chest is found quite filled up by it, and when the symptoms of inanition are marked. It may be called death from pressure upon the lungs and heart when less blood has flowed out than in the case above, when the patient has died under symptoms of suffocation, and when much blood is found in the pericardium.

2d. In penetrating wounds of the heart, from which death has followed later, after some days, it should be carefully enquired, in what

manner death has arisen, and whether it might not have been prevented by proper medical treatment.

If death occur only in a later space of time from hæmorrhage and exhaustion, the wound may be declared to have been fatal, for here no help was possible.

If death occur from suffocation at any time, when from the time and symptoms it might be supposed that the wound in the heart had already closed itself, and dissection shews a large quantity of extravasated blood in the cavity of the chest as the cause of death from suffocation, the wound, when paracentesis has not been attempted, cannot be pronounced absolutely fatal. When the extravasation lessens and dissipates itself by reabsorption, without paracentesis, and death occurs without the operation having been performed, we cannot declare the wound to have been necessarily fatal.

If death arise from extravasation of blood into the pericardium, whilst the opening of the pericardium has perhaps even closed itself, the wound is to be pronounced absolutely lethal. The section must in this case shew the extravasation.

When death follows from inflammation of the heart, when in spite of the best treatment, the inflammation proceeds uncontrollably, and has a fatal termination, the wound is to be pronounced as absolutely fatal. This will be the case in young subjects disposed to inflammation, and where a foreign body, as the point of the wounding instrument, remains in the wound. The section here must shew the products of inflammation, and the absence of other quicker operating causes of death. But in heart inflammation, if death follow from manifestly improper treatment, and no causes are found that must necessarily produce inflammation, and the wound be already closed, and all other causes of death be absent, the wound is not to be pronounced absolutely lethal.

3rd. Wounds of the heart not penetrating, which cut the substance of the heart, without passing into either of its cavities, cannot any longer be considered as absolutely lethal. As these for the most part can only become fatal through the consequent inflammation, so is it valid reason to assert that death is caused by the consequent inflammation of the heart. They can, therefore, only be pronounced as necessarily fatal, when, notwithstanding the most proper treatment violent inflammation comes on, which terminates in death,—in individuals, who are much predisposed to inflammation, in cases, where a foreign body remains, &c.* but even also in the last case, where foreign bodies remain, healing is yet possible, as individual examples have shewn. The accuracy of the treatment must depend upon the history of the case, and the section afterwards must shew the products of the fatal course of the inflammation. But those wounds ought not to be pronounced as necessarily fatal, where the treatment was manifestly bad, when not the inflammation of the heart, but other circumstances have been the cause of death, as in the case presently to be cited from Neurohr. The case of Neurohr affords an instructive example of the kind. He, 19 years ago, pronounced such a heart wound to be not absolutely lethal, while the treatment was notoriously bad, which instead of extinguishing the inflammation, must have necessarily caused its augmentation, although death here was not caused by inflammation of the heart, but through the conflict of other causes, and was brought on especially by the irritating treatment. There was a wound one inch long and three lines broad, which went through the common integuments, and cut through the cartilaginous portion of the 4th rib on the left side, three lines from the sternum. This wound pierced through the pleura from without in a somewhat oblique direction, cut through the left lung, at its innermost end, half an inch in length and three lines in breadth. it then, in the same direction pierced through the pericardium, in its upper part, half an inch in length, and wounded the heart just below the entrance of the right ventricle, at its upper convex part, one short line deep, one inch and a half long, and one small line broad. No traces of inflammation were present in the heart, the pericardium contained four ounces of coagulated blood, in the left cavity of the chest was found between 10 and 12 ounces of partly coagulated, partly fluid black blood, which had been poured out by the severed intercostal artery. The pleura was free, no where adhering. The lungs were somewhat collapsed, yet normal; only where the left lung was wounded, inflamed spots shewed themselves from one and a half to three inches in circumference, yet without passing into suppuration or gangrene. During the course of the sickness, which continued 10 full days from receiving the wound till his death, the patient had difficult, anxious breathing, pain, stitches in the breast, small frequent pulse, strong fever, and great restlessness. The treatment was throughout faulty; no bleeding was attempted, no cooling aperient medicines were given. Instead of these, in three days from receiving the wound, nourishing diet, bark internally, cataplasms of wine and aromatic herbs. After a period of 10 days the patient died under great restlessness, quiet delirium, great dyspnœa, intermitting pulse. Neurohr here rightly judged that the wound was not necessarily fatal, but that death was caused from external circumstances, from the want of proper treatment, but nothing in the wound necessarily produced death in the lungs little, and in the heart no traces of inflammation were found, the treatment was throughout vicious, and no attempt was made to empty the chest of the extravasated blood,* which at length by its pressure and pernicious quality, brought on paralysis of the lungs and heart, with which the extravasation into the pericardium had freely co-operated, which nevertheless by itself alone could not have produced death.† That such wounds can, indeed, be again healed, the case communicated by Ollenroth, among others, fully proves, where the pericardium, and even the apex of the heart, together with the lungs, were wounded. A soldier had wounded himself with a knife where the 5th and 6th rib united themselves with their cartilages. After the wound had been dilated, one might discover a wound in the lung, the pericardium, and a superficial wound in the apex of the heart, which was six lines long. With the finger one might perceive how by the systole, the heart lengthened itself, and touched with its somewhat outward bowed apex the 6th rib, but by the diastole it shortened itself. The motions of the heart appeared to resemble the screw-like movements of a spiral spring. Whilst the heart contracted itself, the arteries dilated themselves; namely, when the point of the heart touched the finger, the radialis dilated itself. When after four or five beats, the pulse intermitted, so was the systole of the heart labouring and trembling. Bleeding was frequently used, and healing followed.*

4th. Wounds of the coronary arteries are absolutely fatal, for here, from the unceasing motion of the heart no closing of the arterial wound can be expected, and no help is possible — it may be that only a very small twig of the artery is wounded, which yet may close itself again.

5th. Ruptures of the heart which are caused by violent pressure on the chest, are absolutely fatal. Examples of this kind may be found in former as well as in latter times.† Death, indeed, here follows from the sudden filling of the pericardium with blood, which is permitted no exit, and which suddenly paralyses the heart not accustomed to pressure. Thus death follows quicker than when through other occasions a sudden outpouring of blood takes place into the pericardium.‡

* Neurohr in this case wrongly ascribed the death especially to the pressure of the extravasated blood. The paralysis of the heart and lungs might easily have been induced by so heating a treatment.

† Judicial inquiry upon a person who died after 10 days from a wound in the heart, by Dr. G. A. Neurohr, in Henkes Zeitschrift, 1825.—Hft: 3, S. 133.

PERISCOPE OF THE WEEK.

Muscularity of Arteries.—I feel a degree of confidence, says Dr. T. H. Moore, of Dublin, advocating in unequivocal terms that the fibres of the middle coat of the large and small sized arteries, be their calibre what it may, are essentially muscular; that they possess the appearance, the arrangement, the physical and chemical properties, and are subject to the same pathological lesions, as the muscular fibres in the tubular apparatus of the lungs, and the fibres in the different divisions of the alimentary canal; all which properties, however equivocal, anatomists, physiologists, and chemists, may pronounce them to be in the healthy condition of the artery, yet are rendered so manifest in the pathological lesions to which these vessels are subject, that they are more than sufficient to dissipate our doubts, and confirm these statements. Who, in the current year, would have the hardihood to assert that the bronchial tubes of the ternary, quaternary, or septenary order of bifurcation, were destitute of muscular fibres, because to the eye of the anatomist they are often invisible; by the hand of the anatomist they frequently cannot be traced; and in the analytical experiments of the chemist, they may be found deficient in that proportionate quantity of fibrine entitling them to rank as muscular? Who is that physiologist, be his experiments performed with the most exquisite dexterity, who has succeeded in producing contractions of the muscular fibres in the bronchial tubes by the electric and galvanic stimuli, even though he employ triple the number of plates with which he failed when experimenting on the middle coat of the arterial tubes?—In a variety of pathological lesions of the arterial system, the preparations of which were subjected to microscopic examination, the formation of small circumscribed accumulations of yellowish-coloured particles has been noticed, varying considerably in size, from a pin's point to the circumference of a silver penny; and in consistence, from a state of perfect fluidity to that of thick cream, collected into a soft pulp or pap, which, when washed away, an eroded, irregular, jagged depression was distinctly apparent: the continuity of the fibres of the middle coat being intercepted, and, as it were, destroyed by ulceration. To such a degree had this destructive process progressed, that the external cellular tunic has been visible

‡ Salzmann de subitanea morte a sanguine in pericardium effuso. Argentor 1731.—Metzger's system des Gerichtl, A. W. 4 Aug. S. 137.

underneath, and when held to the light was perfectly diaphanous; whilst the internal lining serous membrane, covering these yellow-coloured patches, had lost much of its natural polish, was discoloured, hypertrophied, rugous on its surface, in many places thrown into small but distinct folds, easily separable from the middle coat; but very seldom have I seen in this diseased condition of the artery an abrasion of its surface; whilst a complete dissection has been performed between it, and the middle coat, by the process of suppuration, which had originated in it, was confined to, and progressed during the patient's life-time, amongst the muscular fibres of the middle coat.

Onyxis.—The diseased lateral growth of the nail of the great toe, when it presses into the surrounding soft parts, and causes a fungous granulation to spring forth, may be cured by the application of Vienna paste to that portion of the matrix of the nail, which corresponds to the part involved in the vicious growth. The adjacent parts are to be protected by adhesive plaster. By the destruction of the matrix, the reproduction of the diseased nail is prevented. The Vienna paste is the potassa cum calce, prepared with six parts of quick-lime and five of pure potass.

Iodruet of Potassium in Syphilis.—Dr. Langevin, of Havre, has detailed a series of cases of secondary and tertiary syphilis, in which he found the internal administration of the ioduret of potassium in large doses of exceeding service, in every instance effecting a speedy and sustained cure by its use. The first case he details is that of a young man, twenty-five years of age, who had injured his constitution by excesses, and still further by repeated mercurial salivations, which had occasioned alopecia and the loss of his teeth. When he consulted Dr. Langevin, besides syphilitic exostoses on the ribs and nocturnal pains, his left elbow was converted into a semi-spherical tumour as large as a full-grown fœtal head, smooth, hard, and polished. The skin was free from redness; the fore-arm was flexed at an acute angle on the arm, and both were atrophied. None of the bony protuberances of the joint could be distinguished. Two scruples of the ioduret of potassium, in a quart of infusion of saponaria, were given daily for eight days, and the dose was then raised to four scruples for the next eight days, at the expiration of which time the tumour was lessened in size one-half. Eight scruples a-day were then ordered for a fortnight, and then the elbow had resumed its normal shape and size; the condyles could be distinctly felt in their proper situation, and the powers of flexion and extension were restored. The costal exostoses had also disappeared; the nocturnal pains had ceased from the fourth day. During the treatment the patient had a voracious appetite, some redness of the eyes, headache, and dryness of the throat, which were easily removed. This case occurred two years ago; there has not been any relapse, and the patient still enjoys excellent health. The second case is one of chronic syphilitic sore throat, involving all the soft parts; Dr. Langevin prescribed the ioduret internally in the dose of two scruples (afterwards raised to four) daily, an ioduret gargle, and an ointment containing a large proportion of the same salt, which he directed to be rubbed in night and morning over the right testicle, which was affected with sarcocele. The patient was perfectly cured in every respect in three weeks, and has not since suffered a relapse. The third case is one of extensive syphilitic ulceration of the elbow, cured in three weeks by the use of an ioduret wash, and the internal exhibition of large doses (from four to eight scruples) of the ioduret of potassium in an infusion of dulcamara. The fourth case presented exostoses of every articulation, besides a swelling on the anterior part of the coronal, and of the cervical vertebræ. The fifth was a case of syphilitic sore throat of some standing; and the last was an instance of ulcers on the legs depending on a venereal origin. In all these cases the large doses of the salt already alluded to were freely administered, and in every instance were followed by a rapid cure.

Poisoning by Squills.—A man, fifty-eight years of age, was afflicted with general dropsy from insufficient nourishment, anxiety and great fatigue, unattended by any symptoms of organic disease. From this he was relieved by the use of diuretics and bitters, but the complaint returning, he was induced to have recourse to an old woman, who promised to cure him effectually. In accordance with her directions, he procured some squill cut into small pieces, which he digested for forty-eight hours in nine ounces of white wine. Half this quantity he drank at once, and as it caused violent colic, he thought it necessary to assist its action by taking several spoonsful more, which produced an increase of the colic and severe nausea. These symptoms not having ceased for a moment, after the lapse of twenty-four hours he sent for medical advice; he had then a red and burning face, with cold hands and feet; pulse small and contracted, and the abdomen so tender to the touch, that he could not bear even the sheet over him. He died on the second day in spite of all that could be done for him. From the chemical analysis of the rest of the tincture, it appeared that he had taken altogether, five scruples of extract of squills.

Hemeralopia.—Night blindness, says Dr Forry, is eleven times more prevalent in the southern, than in the Northern divisions of America; in other parts of the United States it is almost unknown. In Florida it may be regarded as endemic. The pathology seems to exist in an exhaustion of the power of the retina, in consequence of exposure to strong light during the day; or in other words, vision ceases, because the retina, after having been exposed to a long and brilliant sunshine, is not excited by the feeble light which continues after sunset. The disease is consequently rarely met with, except in the southern latitudes, or those regions in which the ground is covered many months with snow. In Florida, as in the West Indies, the causes productive of it, are, the full glare of a vertical sun in an unclouded sky, and the reflection of the solar rays from the surface of water or from a sandy soil. Its duration in Florida varies from one night to six or twelve months, whilst relapses are frequent. The treatment which is modified in accordance with the accompanying functional derangement, usually consists in confinement to a dark room, the use of emetics and cathartics, and the application of cupping-glasses and blisters to the temples and nape of the neck; but these remedies, as well as salivation, prove in many cases wholly unavailing. When remedial measures fail in tropical regions among those from Northern latitudes, a return to one's native clime is obviously indicated.

Mercurial Frictions.—Mr. Toogood, of Bridgewater, gives three cases shewing the great benefit of mild mercurial frictions in eradicating those complicated symptoms, following at various intervals, venereal disease ill-treated. The success was marvellous in cases of great obstinacy.

Mortality.—The French papers have of late quoted from a work entitled "Les Centenaires," some astounding statements respecting the age attained by individuals in the different countries of Europe. Thus, we are told, that "There have died in England, in the course of the last century, 49 persons who have reached from 130 to 180 years of age! Of those, seven reached 134 years, four 138, two 146, four 155, one 158, one 160, one 68, one 169, and one 175." Now, we believe it to be beyond the power of the writer *to prove* any *one* of these assertions; to prove that any one man or woman, in England, ever attained the lowest of these ages, or 130 years. We do not, of course, mean when we speak of proof, the gossiping nonsense which passes current on such occasions, but such evidence as would be received as conclusive in a court of law; and surely in a country where every parish has its register, the age of a party is a fact very easy of proof. Some years since we were drawn into a controversy respecting the age of a man of the name of Patrick Gibson, of whom a portrait and a memoir were published, setting forth that he was in his 111th year. We proved to demonstration that every assertion from which his great age was to be inferred was false; yet since then, his portrait, with the falsehood deliberately written on the frame, has been placed in the Hall at Greenwich Hospital. Our incredulity on the subject of these Old Gibsons, Old Parrs, and Old Jenkins being known, we have on more than one occasion been sent by friends in search of cases, that admitted, they said of no doubt; but on enquiry, it turned out that instead of "no doubt" we should read "no proof." The parties indeed recollected, or rather professed to recollect, many circumstances which occurred more than a hundred years before, but in no instance could they recollect where we might procure a copy of their baptismal register. This question is not altogether one of mere idle curiosity; the length of time that men may live must affect questions of annuities insurance, and other like calculations; yet, though every season brings forth new insurance companies, new life tables, new expositions and illustrations of the subject, no writer, that we are aware of, has devoted a single chapter to a careful investigation of the age which men have attained.—*Athenæum.*

Microscopic Anatomy of the Brain.—Fontana discovered that the nervous fibres were tubular, the sheath consisting of a transparent membranous cylinder, and the contents, as he supposed, of a gelatinous and consistent humour. By more recent observation it has, however, been established that the nervous matter, or neurine,—which is during life fluid and transparent, the soft, solid, and opake character which it presents soon after death, being the result of coagulation,*—may be distinctly observed with the naked eye in the retina, which, if examined in an animal just killed, is seen to be, as it is in life, diaphanous, whilst in a few minutes it assumes that resemblance to ground-glass with which we are familiar. Professor Valentin, in a course of observations made upon the nerves of living animals, believes that he had detected on the inner aspect of the membranous tube of the nervous fibre a ciliary epithelium.† If this structure should be confirmed by a more extended observation, it would follow that

* This may be regarded as an established fact because it does not rest solely on microscopic examination for the change.

† This observation is, to a certain degree, corroborated by Remak, who has described the ciliary motion in nerves, but he places it in the sheath of the primitive bundle, or fasciculus, not, as Valentin describes it, within the sheath of the ultimate fibre itself.

some kind of motion or current of the nervous fluid is effected by ciliary motion.—Another step has lately been effected, by determining, with the aid of the microscope and minute injections, the disposition of the capillary blood-vessels in the grey matter. How entirely, says Mr. Granger, the prevailing notions respecting the brain would be changed, if, instead of regarding it as a solid body composed of soft fibres, amply, indeed, supplied with blood, but in a manner altogether unknown, we should consider the cerebrum as consisting essentially of an almost infinite multitude of tubuli filled with fluid. I say nothing of their supposed ciliary currents, penetrated by a vast number of arterial and venous canals, carrying, in a definite and ascertained direction, the circulating fluids. It is needless to point out the light which views like these would throw on the pathology of the brain, or to show how powerfully they would illustrate the important views of Dr. Abercromby respecting deranged conditions of the cerebral circulation. If caution is required in the case of the healthy organisation, it becomes much more so when diseased structures are concerned. The important discoveries respecting cells have undoubtedly afforded some facts which promise interesting results regarding morbid growths; for when it is known that a cell can, in virtue of its own independent endowments, take up, from a surrounding fluid, peculiar substances, and increase in the manner noticed, so as to give rise to the various organised tissues, woody fibre, bone, or muscle, we can at all events understand that, owing to some derangement of these processes, morbid matters may be produced or taken up, and abnormal cells generated; phenomena which, according to Müller and others, do take place in carcinomatous tumours, and in tubercle, according to Gulliver. It is also probable that the information we have acquired from the physiology of cells will ultimately tend to explain many of the apparently conflicting views of Hodgkin, Cruveilhier, Müller, and others, concerning the respective influence of the blood-vessels and cellular tissue in the production of cancerous growths; for, as there is such an analogy in the laws which govern the first formation of vegetables and animals, it is not unreasonable to suppose that, as in cryptogamic and vascular plants, growth may take place either by the action of cells alone, or by vessels and cells in conjunction; so in scirrhus, fungus, and colloid, the morbid growth may depend on the action and development of cells alone, or in combination with the capillary blood-vessels. It must, however, be confessed, that at present the microscopic investigations of disease have produced but few well-established and generally-recognised truths. Even in the case of morbid fluids where, *a priori*, we should have expected more satisfactory results, much uncertainty prevails; thus one of the most interesting circumstances to the medical practitioner, the unequivocal distinction, namely, between mucus and pus, is a desideratum yet to be obtained; for not only are there diverse discrepancies in the accounts given of the physical characters of the two fluids, by those who admit a distinction between them, but some eminent authorities, Henle, Barry, and Mandl, state that the globules of pus, and mucus cannot be distinguished from each other.

The Corda Tympani.—M. Guarini adopts the opinion that the corda tympani is not derived from the cranial branch of the vidian nerve, but takes its origin from the facial. He concludes, therefore, that it is, like the facial, a motor nerve. In the second place, he shows by dissection that the corda tympani is distributed principally to the fibres of the lingual muscle, and he thinks that it communicates a motor power to them. To verify this opinion, he performed experiments on animals; striking them on the head, and then quickly making a section of the tongue and the inferior maxillary bone in the mesial line. After waiting till the spasms which affected the muscles had ceased, he implanted one of the needles of a small galvanic pile in the anterior part of the tongue, and connected the other with the nerve whose function he desired to ascertain. He found that when the hypo-glossal nerve was galvanized, the tongue was moved forwards and backwards, upwards and downwards, with such rapidity, that the whole organ appeared convulsed. At the same time the muscular fibres in the centre of the tongue remained unmoved. When the needle was applied to the branch of the fifth pair of nerves no movements of the tongue ensued, nor when the glosso-pharyngeal nerve was touched. If the facial nerve was galvanized the tongue was carried upwards and backwards, then downwards, then again upwards, at the same time undergoing a sort of vermicular movement from the action of the lingualis muscle; the movement upwards and backwards being due to the contraction of the stylo-glossus, the upper part of which receives branches from the facial nerve by means of the corda tympani. These experiments were repeated several times with perfect success by M. Guarini, in the presence of his colleagues. It being doubtful how far the vermicular motion of the tongue might be attributed to the action of the stylo-glossi muscles, these muscles, together with the stylo-pharyngæi and digastrici, and the hypoglossal nerves, were divided, the head having been separated from the body, and the corda tympani and lingualis muscles left entire. The facial nerve being then galvanized, the tongue was no longer carried backwards, but the vermicular movement continued unimpaired. The physiological conclusions which the author draws from these experiments are, that the hypoglossal is not the only motor nerve of the tongue, and he considers that by its influence upon the lingualis muscle the corda tympani is subservient to the articulation of sound.

Creosote in Sea-sickness.—A gentleman, a great martyr to sea-sickness, had been advised to take the creosote mixture; but it had had an effect directly the opposite of what was intended. On the first dose he was seized with retching. Upon the following day the gentleman became exceedingly sick. He applied again to the reputed specific, when the very same dose that had on the previous day made him squeamish, on this trial almost entirely relieved him. *It is worthy of remark* (says Dr. Cormack, who relates this incident) *that creosote, though excellent in allaying vomiting, often excites it when it does not exist.* Vomiting is caused by creosote very frequently where the dose is too large.

Remarkable Case of Ascites.—A woman, aged 36, was attacked in 1823, by a chronic entero-mesenteritis, accompanied by marasmus, suppression of urine, and irregular menstruation. By degrees the abdomen became of enormous size, from the presence of fluid accumulated in the cavity of the peritoneum. The first tapping gave issue to twenty pounds of a lemon-coloured limpid fluid, and M. Lecanus ascertained, after the sinking of the abdomen, that it contained enormous indurations. Ten days afterwards she was again tapped, and so rapidly did the fluid accumulate, that it was necessary to repeat the operation every six, eight, ten, or at the utmost twelve, days. Fifteen years had elapsed in this manner, and tapping had been performed 810 times, when Dr. Lecanus thought of trying compression on the abdomen with pieces of paste-board covered with linen. This remedy employed gradually, at first retarded the accumulation of the fluid; and at the end of six months, during which tapping was practised at more or less distant intervals, it was perceived that the ascites no longer returned. The patient has now been cured these two years, having undergone tapping 866 times during 15 or 16 years. Once only the epigastric artery was opened; but the hæmorrhage was promptly arrested by tents steeped in a styptic liquid, and introduced into the wound made by the trocar.

Treatment of Fractures.—Mr. Grantham, of Crayford, publishes some sagacious observations on this subject. He would keep up the action and temperature of the cutaneous structure, by the use of hot, stimulating applications, which tend to lessen the pain, and quicken the reparative action of the parts, and would forbid the application of cold to the diminution of power produced by local bleeding near the injured part. "We must consider," he says, "the lowly organized state of these structures, which are only balanced or supported in their normal action or temperature by the power of the exhalent vessels of the skin. Did these lower structures but contain one drachm of blood more than in their normal condition, the result would be inflammation, which would require three months at least to effect a termination by resolution. It is a fact, that excitement of the arteries in the vicinity of an injury, assists much in the restoration of a sanative action. Only diminish the power of the arteries and exhalents below the natural standard in such injuries, and you deprive the limb of the means of repairing the mischief, and too frequently bring on phlegmonous inflammation or sphacelus."—Mr. G. adds, as a suggestion, that Galvanism applied moderately, and with the foot or head immersed in hot water, would be useful in regaining the use of the suspended power of a limb.

Odd Midwifery Case.—Mr. Bell, of Burrhead, recently delivering a strong healthy woman of a large female child, had occasion to extract the placenta, in doing which his fingers were severely pricked. On examining the placenta, he found a number of small sharp points attached to it. On more minute examination, its uterine surface was found to be covered with a milky-coloured membrane, which was thickly studded with small points of bone, as sharp as pins, about one-eighth of an inch in length, and about the thickness of a fine sewing-needle. On examining the substance of the placenta, it was found completely filled with these points, but they were of a much larger size, some rather more than two inches long; they were running in every direction, ramifying not unlike the air-tubes in the lungs. The umbilical veins presented nothing unnatural; but the artery, at its termination, was partially ossified. No hæmorrhage, but severe after-pains.

Empyema.—M. Faure wishes to show that in most cases of purulent effusion into the thoracic cavity, paracentesis thoracis is the only means we have of rescuing the patient from almost certain death, and that the operation has been too much neglected.—He asserts that puncture of the chest with a trocar does not expose the patient to the danger of air being introduced into the pleura, and that the wound often closes in forty-eight hours,—that 200 persons die annually, whose lives might be

prolonged or saved, and relates the cases of three soldiers on whom he operated in April and May last. They had been reduced to a very dangerous state by the effusion. One died a few days after the operation, but the other two were still alive, when last heard of on the 31st of July.

Structure of the Lung.—M. Bourgery, writing on the relation between the structure of the lung and its functional capacity in both sexes and at different periods of life, gives the measurements of the minute pulmonary apparatus in the adult; and then passes to the microscopic examination of its texture at different periods of life. He shows that the development of the aerial and sanguineous capacities of the pulmonary apparatus is much influenced by age, appearing to be in inverse proportion at the two extremes of life. In infancy the vasculatory and aerial capacity of the lung are very great, and this perhaps, may occasion the extreme plasticity of the blood at this period. The great energy of the respiration, arising from the full but equal development of the sanguineous and aerial systems, is characteristic of adolescence, and manifests itself by the rich qualities of the blood peculiar to puberty. In the adult the respiratory apparatus remains stationary for some time, but as years go on, the air-cells partially give way and the blood-vessels become obliterated, and old age ensues with its feeble and impoverished circulation. From these facts the author thinks that, in a general point of view, man at his different periods of life presents an analogy to the two classes of vertebrate animals in which the extremes of the respiratory functions are observed. As he approaches towards puberty the lung is gradually developed, and offering every year larger and larger surfaces to the air, gives rise to a function similar to that of the bird. In old age, on the contrary, the lung is gradually broken up into air cavities of increasing magnitude, while the circulation is diminished in the same proportion; and thus the respiration, both in its real capacity and in the structural changes of the organ effecting it, assumes the characters peculiar to reptiles.

Detection of Albumen in Urine.—The solubility of albumen in nitric acid, as a source of fallacy in detecting albuminous urine, has, I think, says Dr. J. W. Griffith, been entirely overlooked by writers on urine. The ordinary method of proceeding is to heat the urine to the boiling point, and then to add a few drops of nitric acid, when, if the precipitate be redissolved, albumen is considered absent; if otherwise, it is regarded as present. When the urine contains albumen in large quantity, the appearances produced by its coagulation are so characteristic that they cannot be mistaken; it is only where there is a moderate or small quantity present that any error can be made. The strong acid being generally used, I shall confine my observations to it.—When a few drops of nitric acid* are added to urine† containing a small quantity of albumen, a cloud is immediately formed, which, by agitation, is entirely redissolved: so, after heat, a drop or two of acid added and the fluid agitated, the albuminous cloud disappears; a few drops more added, throw it down again; and a further considerable excess redissolves it. Therefore, the formation of a cloud by heat, which is soluble in a drop or two of nitric acid is no proof that albumen is absent. The value of the nitric acid test depends entirely upon the proportion added. The mere adding a few drops is not sufficient, moderate excess ought to be used. The quantity of acid required for the above-mentioned second solution is, on an average, at least as much as the bulk of the urine used; so that by always using considerably less than its bulk, this chance of error may be avoided. The cloud of phosphates precipitated by heat is very readily dissolved in a small quantity of acid; and by adding a few drops more it is not again precipitated. This then, would readily distinguish the phosphates from albumen.

* Specific gravity, 1·5.

† I suppose the operator to be using about six drachms of urine.

MEETINGS FOR THE ENSUING WEEK.

Octr.	31, Monday,	Medical Societies of London, 8 P.M.

	5, Saturday,	Mathematical Society, 8 P.M.

MEDICAL NEWS.

London Royal Infirmary for Children.—A vacancy has occurred in the physicianship of this institution by the retirement of Dr. Willis.

French.—A most satisfactory decision has been recently adopted by the administration of hospitals in France, with regard to the treatment of idiotic children. Our readers may, perhaps, remember that M. Seguin, a young philanthropist, who devotes himself to the education and instruction of idiotic infants had proposed to submit to his method a certain number of individuals taken out of the asylums. The administration of hospitals on the report of M. Orfila, acceded to his demand. Twelve children were entrusted to him from 8 to 16 years of age, taken from the hospital of *Incurables*, and who were considered to be in a state of hopeless idiotcy. None of them could read or write, several had with difficulty accustomed themselves to use a few words, while the others emitted only inarticulate sounds; some were epileptic, and three or four were subject to constant convulsive movements. After a twelvemonth's treatment, M. Seguin has presented these children to a commission, composed of MM. Fouché, Halpher, and Orfila. These gentlemen have become satisfied that all these children are now able to read, and some of them can write from copy; that almost all speak distinctly, and that they answer correctly to the questions put; some can perform addition, substraction, and even multiplication. They have also become physically improved; so that these children who were but an encumbrance to the house, are now capable of great service. The administration considering these results, has decided that M. Seguin, who hitherto had been authorized merely to make trials, should have an express authority for continuing them upon a larger scale, and should, for this purpose be lodged, boarded, and remunerated. A special allowance will be demanded for this object by the general administration of this department. We hail with pleasure the commencement of an undertaking of such vast interest.

The Prefect of Police of Paris has lately issued a new ordinance, dated the 15th of Sept. for the regulation of knackers. They are in future to have closed carts, so as not to allow their contents to be seen; these vehicles are, moreover, to be so constructed as not to allow the escape of any liquid. Animals destined for the knacker are not to be allowed to enter Paris. No animal is to be slaughtered within the city. The knackers are all to live outside the barriers. All animals dying in the capital are to be removed during the night, between the hour of midnight and six in the morning. Animals known to be affected with contagious diseases, are not, under any pretext, to be stationed within the city. Lastly, upon any requisition, the knackers are bound to remove dead animals, in conformity with the preceding regulations.

The same magistrate has also issued another order which essentially concerns the proprietors of hotels, the chiefs of establishments, shopkeepers, &c. who employ gas in lighting their houses. This order points out the care and precaution to be used with gas fittings, so as to guard against accidents. It especially directs the careful ventilation of places in which gas is burned, the employment of stop-cocks which shut with precision, and which should be frequently oiled; besides these stop-cock at each burner, it enjoins a principal cock which is to be turned off as soon as the lights are put out. Immediately that a smell of gas is perceived in an apartment, the doors and windows are to be thrown open, and notice directly given to the gas-fitter belonging to the company. Lastly, when an escape of gas becomes ignited, they are to endeavour to extinguish it by wetting a cloth, and quickly applying it upon the inflamed jet. That nobody using gas should forget these directions, the various companies are ordered to have them printed at the back of their monthly receipts.

St. Thomas' Hospital.—On Friday evening, the 21st inst., the first microscopic entertainment for the session was given at the great hall of the hospital. The business of the evening was opened by an address from Mr. Grainger, by whom the chair of physiology in this school is now filled, on the state, and amount of our present knowledge, as developed and established by microscopic research. A summary survey was taken of the more important and recent contributions, with which the German observers had enriched the science of organization. Those of Schleiden and Schwann on the relations of the cytoblasts and cells in the production of all forms and variety of organic structure, and the remarkable identity which their labours have proved to exist between the laws which regulate these primordial forms of living matter in the animal and vegetable kingdom—were introduced as the highest in value of any with which the domain of physiology had been evidenced in modern times. In connection with the subject of nucleated cells, Mr. Grainger passed a high eulogium upon the investigations of Dr. M. Barry into the occult and early changes which mark the commencing development of the new being. It was proved by his labours that the first discoverable step in this process, consists in the formation of a nucleated cell, or cells, which correspond in character with those which the German observers have shewn to constitute really the origin of all forms of structure. The interesting subject of the several phases which the spiral variety of vascular tissue was capable of assuming, were most lucidly explained by the assistance of diagrams. He alluded particularly to the fact that the annulated, the dotted, the pitted ducts observed so abundantly in vegetable tissue, were traceable to the spiral form as a common origin. It was shewn also that it was quite philosophical to admit great analogy as regards the plan and process of formation, between these spiral structures of vegetables and the tracheary apparatus of insects, birds, and mammalia. The last subject noticed was that which by far excited the greatest curiosity and interest; it related to the minute structure of the muscular fibre of voluntary motion. A clear and simple exposition of the prevalent and conflicting views was given—of that first entertained by Mr. Bowman, which supposes the primitive fibres, to be made upon flattened cells, or discs,

placed in contact upon their flat surfaces, or that, secondly, maintained by Dr. Martin Barry and Dr. Leeson, according to which it was conceived that the same primitive filament was composed of a double spiral. He remarked that this formation had been fully made out by Dr. Leeson, six months before the observations of Dr. Barry. He did not attempt to decide on the merits of these two views—stating from the evidence of Dr. Leeson's preparations more particularly, that there could be no doubt as to the *existence* of the double spiral in the filament, whatever its nature may be. In the theatre of the hospital, the phenomena of polarisation were beautifully exhibited by Dr. Leeson, by means of the oxygen-hydrogen-microscope. In addition to a great variety of other highly-interesting objects, we observed it as a pleasing triumph to microscopic science, that the long table of the hall was crowded with lamps and the most valuable microscopes, giving to the room a very brilliant and imposing effect.

Among the company present, which consisted of nearly six hundred persons, comprising many German and metropolitan professors and men of science—were:—R. H. Pigeon, Esq., Treasurer of Christ's Hospital; James Bentley, Esq., Treasurer of St. Bartholomew's; the Prince of the Druses, Beyrout, Antonius G. Aumrie, Beyrout; Le Capitane Nagy de Golantha; Professor Mitcherlitch, Berlin; Professer Capari; Dr. Dieffenbach; M. le de Stoll; Sir George Lefevre; M. Williams, Esq., M.P.; Professor Brand; Professor Cooper, — and many other distinguished men. The company did not separate until a late hour. Tea and coffee were liberally provided in the committee-room, adjoining the great hall.

ROYAL COLLEGE OF SURGEONS, LONDON.

List of gentlemen admitted members on Friday October 21st, 1842:—

H. D. Marchant, C. Wrixon, H. H. Hole, J. A., M'Donogh, J. J. Horton, J. Lancaster, R. Bunce, E. Haddock, H. Hill, C. Bond, W. E. Taylor, R. W. Wollocombe, J. Gerrard, W. M. H. Day.

TO DISPENSING CHEMISTS.

Just published, price 5s., Third Edition.

A GRAMMATICAL INTRODUCTION TO THE LONDON PHARMACOPŒIA, AND A KEY TO LATIN PRESCRIPTIONS.

By S. F. LEACH. The former Editions of this book were adapted principally to the wants of the Medical Student, the present is considerably extended, so as to meet the requirements of all those who are concerned in making up and dispensing Latin Prescriptions. This little work contains a compendious outline of the Grammar and Syntax of the Latin Language; an analysis of the London Pharmacopœia; a Key to Latin prescriptions; and a Vocabulary of all the words used in the Pharmacopœia and Prescriptions. With Rules for the Genders of Nouns and Conjugations of Verbs, &c. It also includes a list of the former and New Names of Medicinal Preparations, the Tables of Chemical Elements and Symbols, a description of English Measures, the Abbreviations and contractions used in Prescriptions, and a very copious Explanation of many of the formulæ commonly employed.

"This little work will be found extremely useful to students who have received but an imperfect classical education." LANCET, Nov. 30, 1839.

H. HUGHES, 15, St. Martin's-le-Grand.

THE ANATOMY OF SLEEP; OR, THE ART OF PROCURING SOUND AND REFRESHING SLUMBER AT WILL.

By EDWARD BINNS, M.D.,

Member of the Society of Antiquaries of Scotland, &c., &c.

EXTRACTS FROM PUBLIC JOURNALS.

"The philanthropic purport of Dr. Binns, is to teach those unhappy people who may be subject to the severe visitation of insomnolence, 'the Art,' as the learned Doctor designates his prescription, 'of Procuring Sound and Refreshing Slumber at Will.' A rare philosophical work; an apposite and curious treatise." Morning Herald, Sept. 28, 1842.

"Dr. Binns gives a general view of the Physiology of Life, tracing its progress from plants to man; he enters into an elaborate description of the brain; he treats of sleep in all its various phases; generally speaking, he confines himself to cases in fact, of which he has collected a vast number." Spectator, Oct. 5, 1842.

"This treatise exhibits a vast mass of exceedingly curious and interesting matter, the fruit of extensive reading, research, and personal observation. One of the great merits of Dr. Binns's volume is, that it is entirely suggestive. We have ourselves been much interested and gratified in the perusal of the volume before us." Naval and Military Gazette, Sept. 24, 1842.

"How has this been effected?—a medical book, amusing [illegible] as a dictionary, and safe as a sermon? Why, simply by taking 'sleep' as a text merely, and collecting together in a condensed form, all that is known of and 'about' it (not to mention much that is unknown) of strange and wonderful, and note-worthy, from all writers of countries and languages, and ages." United Service Journal for October.

"This is an exceedingly curious and exceedingly amusing book; our author amuses and teases, and informs and tantalizes, and diverts and excites; instead of sending his readers to SLEEP, he keeps them wide AWAKE. The entire volume affords evidence of extensive reading and research, and may be justly regarded as one of the 'curiosities of literature.'" The Court Journal, Oct. 8, 1842.

"Here is a curious book indeed, involving within itself numerous paradoxes, for it is at once excitative and sedative, anti-hypnotic and somnambulic. Dr. Binns devotes a large portion of his work to an enquiry into the nature of sleep. These chapters are exceedingly interesting, being full of illustrative facts, anecdotes, and reminiscences, historical records, and reflections." Liverpool Albion, Sept. 26, 1842.

"We never remember to have taken up a book on a Medical Subject which has so thoroughly interested us, as Dr. Binns's little work on 'The Anatomy of Sleep.' He has gathered, in a most complete form, all the cases which bear upon his subject." The Weekly Chronicle, Sept. 25, 1842.

"This work, in which we, with whom it has ever been a favorite occupation to study how we were made, and what we were made of, have found collected from various treatises that we could name, all the important facts with which the true theory of sleep, whenever it shall be discovered, must be reconcileable. As a hand-book of such facts, as a repository of the tests by which the value of all new systems must be determined, this work is invaluable. In conclusion, we recommend the work of Dr. Binns most strongly, to the unlearned for the solid information which it contains, to the lovers of the marvellous for the delightful and delightfully told stories with which it is filled, and to the learned as a most useful book of reference."—The Catholic, Sept. 24th, 1842.

"The common-place book of a professional man, at once interested in and capable of reasoning upon the phenomena of life. It is full of facts and speculations, and teems with interest independently of its express purpose." The True Tablet, Sept. 24th, 1842.

"No wonder in the heavens above, or the earth beneath, or the waters under the earth, certainly none in past histories, seem to have past the observation of the vigilant eye of the author, or the chronicling of his industrious pen. The conquest of that wayward deity sleep at will too without narcotics, the theory of sleep, the nature of dreams, with the record of all of those of most startling interest,—somnambulism, with its novelties; mesmerism, with its miracles—swoons, trances, asphyxia, with all their incidents; abnormal psychological phenomena, apparitions, hallucinations, and monomania, with all their fantastic freaks, as recorded of the great and eminent, psychology and animal being, with all their absorbing mysteries, these are among the topics, with abundant other subsidiary subjects of equal attraction, which are dilated upon by the author, and with the evident gusto of one who is dealing with a subject after his own heart, and with an interest for the reader which we do not hesitate to say are equal to that excited by a novel of Walter Scott, or a play by Sheridan. Johnson who once confessed to being kept awake for one night in his life, by the 'Anatomy of Melancholy,' by Burton, could by no possibility have escaped a repetition of the extraordinary self-denial he would record, if happy enough to have had the 'Anatomy of Sleep' by Binns. It is the very book the lexicographer would have delighted himself in hugging and gloating over. . . . Here we close our first notice of this treasure for the reading public. The work to our minds is by far the most [illegible] that has issued from the press for many a year, and will at no distant day we confidently predict be found in every man's library." Medical Times, Sept. 17, 1842.

"The Editor of the 'Med. Gaz.' (Oct. 14th) devotes a leading article to the consideration of 'The amusing work of Dr. Binns,' and 'the important facts and theories brought forward by him.'"

"Under this unpretending title we have here a volume redolent with interesting matter, and destined to take its place by the side of Haddon, Scott and Macnish. It is not a simple treatise on sleep, but a complete history of the abnormal functions of the brain, and involving as it does the whole range of physiological and psychological science, it required to be met by a mind versed in the knowledge of organic phenomena, thoroughly imbued with the subject, and above all, having the courage to throw off the shackles of the older metaphysical and scholastic doctrines, and work his way by the aid of modern practical and experimental inquiries. We therefore cordially recommend the interesting volume to young and old readers, and to all to whom the discouragement of long-standing prejudices is a desideratum." Literary Gazette, Oct. 15th, 1842.

JOHN CHURCHILL, Princes Street, London.

MEDICAL BOOKS.—OPERUM HIPPOCRATIS COL. LEGALES GRÆCE ET LAT. CHARTERIUS,

13 Vol. in 9, folio, £5. Paris, 1639. LIZAR'S ANATOMICAL PLATES, Coloured, 12 Parts complete (Last Edition), £4 15s. BLONAM'S SURGICAL ANATOMY of the ARTERIES, Coloured Plates, 12mo, cloth, £1. 10s., published at £2. 1s. TIESON'S ANATOMY and SURGERY of INGUINAL and FEMORAL HERNIA, Coloured Plates, folio, bd. £1. 1s., published at £2 [illegible] 1831. COULSON on the DISEASE of the HIP-JOINT, Coloured Plates, 4to, cloth 7s. 6d., 1837. THOMSON on INFLAMMATION, 8vo, half calf, very scarce, £1. 1s. 4to, 1813. WILLAN on CUTANEOUS DISEASES, 33 Coloured Plates, 4to, half calf, £1 10s., 1808. BELL'S (JOHN) PRINCIPLES of SURGERY, Coloured Plates, 4 Vol. 8vo, bds., £1. 1s. 26. CRUVEILHIER ANATOMIE DESCRIPTIVE, 4 Vols. 8vo, half bound 12s., Paris, 1834. RAYER TRAITÉ DES MALADIES DE LA PEAU. Coloured Plates, 2 Vols. in 1, 8vo, sewed 12s., Paris, 1827.

[illegible] and B. NOCK, 15, TOTTENHAM COURT ROAD, South Side of the New Road, near Gower Street.

*** Upwards of 4,000 Volumes of Second Hand Medical Books constantly on Sale.

On the 1st of November, with two Plates, price 1s. 6d.,

THE LONDON AND EDINBURGH

MONTHLY JOURNAL of MEDICAL SCIENCE.

Edited by Dr. CORMACK.

This Number will contain ORIGINAL ARTICLES by Mr. Benjamin Bell, Professor Syme, Dr. Golding Bird, and Dr. David Smith, an elaborate Review of Works, on Urinary Pathology, abstracts of all that is important in the latest numbers of the British and Foreign Medical Journals, and the Professional news of the day.

TO ADVERTISERS.

From the large and steadily increasing circulation of this cheap and comprehensive Journal, it forms an admirable medium for Advertisements. It is to be found in every part of the united Kingdom, and Colonies of Great Britain, as well as in various towns on the Continent.

Advertisements must be given in on or before the 22d of the month preceding publication.

London, JOHN CHURCHILL. Edinburgh, MACLACHLAN, STEWART, & Co. Dublin, CURRY & Co. Paris, FORTIN, MASSON, & Cie.

ROYAL ADELAIDE GALLERY.

LECTURES on CHEMISTRY, &c., by Dr. AYKIN.

Dr. Atkin commenced a Course of Lectures on Chemistry in the Laboratory of the Institution, on WEDNESDAY, October 5th, 1842, at 9 o'clock a.m., and will continue them every morning at the same hour.

The course will consist of upwards of Ten Lectures, and is intended for persons wishing to study Chemistry, either as a branch of medical education, or in its application to Arts, Manufactures, &c. The modes of receiving and analysing medicine, &c., will be shown and explained. A considerable part of the course will be devoted to organic Chemistry, &c., and a full account given of the late discoveries by continental observers. Fee, Two Guineas.

On the same day a series of Lectures on Practical Chemistry will be commenced, in which the Pupils will have opportunities of performing experiments, applying tests, and becoming familiar with manipulation. Each practical course will comprise forty lessons, and be given at hours to suit the convenience of Students. Fee, Three Guineas.

One Course will be especially devoted to Chemical Analysis. [illegible]

Extended laboratory practice for not less than three months, at the rate of Fifty Guineas per Annum.

Assays and Analyses conducted by the Chemist personally. Mineral Assays from [illegible] to £1. 1s. each. Agricultural and other Analyses on moderate terms.

Gentlemen wishing to carry out special investigations, or experiments for perfecting inventions, may have the use of apparatus and the assistance of the Chemist, by applying to the Secretary.

AINSWORTH'S MAGAZINE.

Price Half-a-Crown, the November Number will contain

THE MISER'S DAUGHTER.

By W. HARRISON AINSWORTH, Esq.

Part XIII.—Chaps. XI., XII., XIII., XIV., XV., XVI., XVII., and XVIII., with Two Illustrations on Steel,

By GEORGE CRUIKSHANK.

Purchasing a Property. By Mr. Pardoe.

The Guerilla of Leon. By Chas. W. Brooks.

The Lion's Ride. By John Oxenford.

The Persian Poet's Tomb. By Catherine Parr.

A Leaf from the "Gesta Romanorum." By Robert Bell.

A few Notes on Mr. Dickens' "American Notes." By Uncle Sam.

The Church of Saint Valery. A Legend of Vaucouleurs. By Charles Hervey.

THE ELLISTON PAPERS.

Part I.

EDITED BY GEORGE RAYMOND, Esq.

The Cholera in Ireland. By W. Francis Ainsworth.

The Portfolio-Wife. By J. Price.

Three Songs. By Edw. Kenealy.

Milton and the Swedish Lock. By Thomas Hughes.

Dr. the Younger. By Laman Blanchard.

The Duke of Wellington and Richard Cromwell. By E. Mc Stone, Authoress of "William Langshawe, the Cotton Lord."

WINDSOR CASTLE.

An Historical Romance,

BY W. HARRISON AINSWORTH, ESQ.

Chapter VI.

WITH AN ILLUSTRATION ON STEEL,

BY TONY JOHANNOT,

And Woodcuts by W. Alfred Delamotte.

Cunningham and Mortimer, Publishers, Adelaide Street, Trafalgar Square.

MRS. SCOLEY, 11, Sidmouth Street, Regent Square,

near Gray's Inn Road, requests the attention of Medical and Law Students to the above address. Drawing-room and Bed-room, Single Bed-room, or a Double Bed-room with Sitting-room if required, with or without Board, on very moderate terms, and at the same time every attention paid to the comfort and convenience of her lodgers.

SKELETONS, SKULLS, &c.

A. ALEXANDRE, Foreign Bookseller, 37

GREAT RUSSELL STREET, BLOOMSBURY, continues to sell at moderate prices the following: Articulated Skeletons from [illegible] Quarter-articulated ditto, [illegible] Separated Skulls [illegible] Skull in Section [illegible] the preparation of the Ear [illegible] Female Pelvis, with ligaments [illegible] Articulated Hand and Feet [illegible] A large collection of all kinds of Loose Bones from Professor [illegible] Skeleton, very cheap.

37, GREAT RUSSELL STREET, BLOOMSBURY.

FRENCH LANGUAGE.

M. DE BEAUVOISIN'S ORIGINAL SYSTEM.

MONS. MARIOT DE BEAUVOISIN (from Paris) begs to inform his pupils and the public that he is now resuming his Classes at his Chambers, 43, Lombard Street, City, and 108, Strand, for the Season. The terms, the days, and hours of attendance are the same as before. A Prospectus may be had at either of M. B.'s residences.

N.B. M. de B.'s Original System is published by SOUTER, [illegible] 131, Fleet Street, and sold by all booksellers and vendors of new publications. Price, each [illegible]

"Every learner should immediately adopt this system." COURT GAZETTE.

"This work is the most useful that has yet appeared,—creditable at once to the skill of the writer, and remarkable for knowledge, acuteness, and judgment." NEW WEEKLY MESSENGER.

"We can recommend it to our readers as being one of the best for acquiring a knowledge of the French tongue." AGE.

"It appears to us to be entirely unique." NEW MONTHLY BELLE ASSEMBLÉE.

"It is the best introduction to the French language we have seen, and the system is calculated to make a sound scholar." MORNING ADV.

"We consider this little work as a decided acquisition." PATRIOT.

"It is on the Hamiltonian system, but with great improvements, &c. The plan appears to us very satisfactory." DISPATCH.

"It partakes of the Hamiltonian system, but in our opinion is infinitely more effective." BELL'S LIFE.

GEORGE HARRIS, WRITER & LABELLER to

the Medical Profession, 17, Little Queen Street, Holborn.

G. H. most respectfully returns his thanks to the Medical Profession, and Chemists and Druggists generally, for the very liberal support he has received as a Labeller and Writer for 20 years, and begs leave to observe, that he now undertakes to fit up Shops and Surgeries in any style of elegance or neatness, and to any price; and trusts, from the great experience he has had with the late Mrs. Willats, Mr. Bruce, and for the last 10 years with the highly respectable firm of Ansell and Hawke, 8, Great Queen Street, Lincoln's-inn fields, that he will be enabled to give satisfaction.

Stoppered rounds 1s. per lb., mahogany fronted drawers, 1s. 11d. each. Labelling in the very best style, 2s. 6d. per dozen. Every article warranted.

DR. STEGGALL continues his LECTURES

and EXAMINATIONS for the College of Surgeons and Apothecaries' Hall, also for the other Medical Boards. His fees are for an unlimited period, consequently pupils would derive increased benefit by entering at the commencement of their studies, thus obtaining a tutor to direct them during their entire residence in London. Dr. S. is quite willing to guarantee their success. Hours of attendance, from Ten till One, a.m., and Six to Nine, p.m., in Chambers, at No. 17, Bloomsbury-square.

ORIGINAL MEDICAL GLASS AND FIXTURE WAREHOUSE.

ANSELL AND HAWKE, of No. 8, Great

Queen Street, Lincoln's Inn Fields, beg to inform Gentlemen commencing or altering in the above Profession, that they have a large assortment of Drawers, Bottles, Jars, and every requisite for complete Shops or Surgeries, on the most moderate terms. Most satisfactory references can be given as to style and quality. Plans and Estimates furnished, free of expense.

Valuation of Stock and Fixtures.

MOSLEY'S METALLIC PENS.—The ex-

traordinary patronage which these celebrated PENS have met with since their first introduction to the public, is a convincing proof of their decided superiority. For ease and smoothness in writing they are equal in every respect to the quill, while their great durability, combined with their cheapness, cannot fail to recommend them to the notice of merchants, bankers, and others, where time and legible writing are appreciated. Another proof of their sterling qualities is the circumstance of their being used in most of the Government Establishments, where only articles of a superior description are admitted. To guard against the many spurious imitations that are palmed upon the public, every genuine pen is stamped "Richard Mosley and Co., London." These pens are sold by all stationers and other respectable pen dealers throughout the kingdom, and wholesale at No. 8, HATTON GARDEN.

PHILOSOPHICAL INSTRUMENTS.

WARD'S CATALOGUE of CHEMICAL and PHILOSOPHICAL INSTRUMENTS

is now ready for distribution, gratis. It is illustrated by 100 Woodcuts, and every article (above 2000) is priced, the Weight under [illegible] All letters to be paid.

THE CHEMICAL CATALOGUE of PURE TESTS and REAGENTS is nearly ready.

Agent for Griffin's Cheap Apparatus and the German Porcelain.

JOHN WARD, OPERATIVE CHEMIST, 79, Bishopsgate Street Within.

GILLOTT'S PENS.

THE QUEEN has been graciously pleased to command that JOSEPH GILLOTT, of Birmingham, be appointed STEEL PEN MANUFACTURER IN ORDINARY TO HER MAJESTY, dated April 19th, 1840.

JOSEPH GILLOTT'S very superior PATENT

and other STEEL PENS may be had of all Stationers and other Booksellers, and other Dealers in Pens throughout the United Kingdom.

[illegible] Public for the [illegible] continually increasing demand [illegible]

The number of Pens manufactured at the Works of JOSEPH GILLOTT from Oct. [illegible] to Oct. [illegible] was [illegible] dozens, or [illegible] gross, and from [illegible] was [illegible] 62 [illegible] 24 dozen [illegible]

CAUTION.—All the Genuine Pens are marked in full "JOSEPH GILLOTT," and vendors are desired to note that Cards of Pens are made up in packets of [illegible] and have a label outside with a fac-simile of his signature.

*** At the request of persons extensively engaged in tuition, J. G. has introduced his WARRANTED SCHOOL PENS, which are [illegible] adapted to their use, being of different degrees of flexibility, and with fine, medium, and broad points.

Wholesale and for Exportation at the Manufactory, VICTORIA WORKS, GRAHAM STREET, BIRMINGHAM, and at 37, GRACECHURCH STREET, LONDON, under the management of Mr. [illegible] the Manufactory at Birmingham, or from any of the Wholesale Stationers in London, &c.

London: Printed and Published by [illegible] at the Office, [illegible] Strand, in the Parish of St. Clement Danes, Westminster, in the County of Middlesex.—October 29th, 1842.

AGENTS: Maclachlan & Son, Edinburgh; Samuel [illegible] Bath; Willmer and Smith, Liverpool; Fannin & Co., Dublin.

THE MEDICAL TIMES

A Journal of English and Foreign Medicine and Medical Affairs.

No. 163. Vol. VII. LONDON, SATURDAY, NOVEMBER 5, 1842. PRICE FOURPENCE. STAMPED EDITION, 5D.

For the convenience of Subscribers in remote places, the Weekly Numbers are re-issued in Monthly Parts, stitched in a Wrapper, and forwarded with the Magazine.—Orders for the Stamped Edition (10s. 10d. per Half year, Post-free in advance,) are received by any Bookseller or Newsman, or may be directed to J. A. Carfrae, Esq., at the Medical Times Office, (late Lancet Office,) London.

SUMMARY.

CASES OF PERITONEAL SECTION FOR THE EXTIRPATION OF DISEASED OVARIA BY THE LARGE INCISION FROM STERNUM TO PUBES, SUCCESSFULLY TREATED.

By CHARLES CLAY, Member of the Royal College of Physicians, London; of the College of Surgeons, Edinburgh; and Lecturer on Medical Jurisprudence, &c. Piccadilly, Manchester.

(Continued from page 62.)

CASE THE SECOND.

OVARIAN EXTIRPATION BY THE LARGE INCISION.

Elizabeth Beswick, æt. 57, applied to me on the 27th of Sept., 1842, in consequence of the abdomen being enlarged by dropsy. I performed paracentesis abdominis on the 30th of Sept., when twenty-five and a-half pounds of fluid were taken away, of a true ascitic character; and it was not till the fluid was discharged, or nearly so, that I discovered in the left iliac region an ovarian tumour about four pounds weight. I was the more surprised at this, as neither the history of the case, nor its appearance before tapping, led me to expect it. The tumour, as well as the fluid deposited, had both been produced within the last ten months; previous to that, no tumour existed that she knew of. She had suffered much from inconvenience, and occasionally from pains about the umbilicus. She had borne nine living children, and does not recollect receiving any injury by blows, falls, &c.; her health had generally been good; she was low in stature, and much emaciated within the last six or eight months. The tumour occupied the left iliac region, and as the abdominal parietes were very flaccid after the water had been drawn off, its character was distinctly visible:—it appeared circular, rather flattened, with a long pedicle, and, though moveable, the parietes in front below the umbilicus were firmly attached to it for the space of two square inches (an adhesion of some standing.) The tumour felt hard and heavy for its size, consequently, I concluded it to be a solid mass, or nearly so; this probable solidity, and its firm adhesion, at once convinced me that it would be impracticable to extirpate it by any other mode than the large incision. In order to allow the wound caused by tapping to heal, I fixed on Friday the 7th of October, at half-past three, P.M., for the operation; the preparations for which were conducted much in the same way as in the case of Mrs. Wheeler, and therefore need no repetition.

On the evening of the 6th I gave her ten grains of the inspissated ox gall, which brought away a copious motion before bed-time without any uneasiness. Five grains more were given early in the morning of the 7th, and another motion was had before noon, with a free and copious passing of urine. She again passed her urine freely, immediately before the operation.

On the afternoon of the 7th, I commenced the operation in the presence of Dr. Radford, Mr. W. C. Vaudrey, Messrs. J. J. & G. Southam, surgeons, and Mr. Higginbottom, nephew to Dr. Radford.—Pulse, before the operation, 70.

OPERATION.

As paracentesis abdominis had been previously performed, and the tumour was of smaller dimensions than Mrs. Wheeler's, the first incision extended from about two inches above the umbilicus to the pubes, or nearly ten inches in length. The parietes of the abdomen were so flaccid that more difficulty occurred in making the first incision, and in dissecting through the peritoneum, than in the first case, where the same were distended. No sooner was the tumour exposed than adhesions presented themselves in every direction. In the diagnosis which Dr. Radford and myself had formed of the case, I fully expected an extensive and long standing adhesion to the anterior of the tumour, immediately in the vicinity of the umbilicus; but from the mobility of the tumour in every direction, (save the exception mentioned,) we thought it pretty free elsewhere. In this we were deceived: adhesions were found in almost every part remarkably strong, and only to be separated with the scalpel. There was also a decided difference in the character of the adhesions: those attached to the parietes were broad and firm in their attachments, whilst the connection with the viscera was by numerous long fibrous bands; it was evidently their length and adhesion to the moveable parts that gave the tumour the mobile character it had. The pedicle, too, being long (as I had anticipated) facilitated the movements of the tumour; the pedicle was broader and thicker than in Wheeler's case, and when cut through, one of the cysts discharged about four pints of fluid. In this instance I passed a strong double ligature through the central expansion of the pedicle, and tied it both ways; thus securing it by two ligatures, which appeared to be quite sufficient to secure the vessels of the pedicle from pouring out blood, as they did in Wheeler's case, were they had to be separately tied. The adhesions were overcome by the scalpel, and their number was more than expected. The whole blood lost in the operation was trifling,—certainly not more than two ounces. The uterus (with the rest of the viscera) was perfectly healthy; the intestines not in the least distended, with either flatus or fœcal matter, and in no way impeded the operation—a circumstance which I again attributed to the effects of the inspissated ox gall, which she had taken the night before. The parietes were secured by seven interrupted sutures, with straps of adhesive plaister between, side straps, with pads of linen, and bandages over the whole. My patient was quite equal to the task she had undertaken: scarcely a word fell from her lips indicative of pain,—on the contrary, she replied to any question with great composure, and drew comparisons between the sufferings of parturient efforts and the operation,—concluding that she had had worse labours, as to suffering pain, than the present operation. After the operation she complained of pain in the left iliac region and the loins, evidently owing to the stretching of the adhesions, but more particularly the pedicle. The whole time consumed in the operation was about ten minutes, and in about twenty-five minutes from the commencement she was placed comfortably in bed; and, what was most extraordinary, the pulse had scarcely varied a single stroke from what it had been for the last two days. I gave her a draught with three-fourths of a grain of mur: morphine, with one ounce of camphor water, and left her very composed, if not really cheerful. Before I proceed with the details of the case, I will briefly describe the tumour itself, as some very important circumstances are connected with it.

DESCRIPTION OF THE TUMOUR.

It will be recollected that paracentesis abdominis had been performed in this case, previously, and the amount of twenty-five pounds-and-a-half of fluid of the true ascitic character had been drawn off, and it became of importance to know of a certainty if this fluid was really ascitic or had been contained in the ovarian sac. The form of the tumour was an oblate spheroid, and when perfectly emptied of its contents the solid part weighed very nearly five pounds; it was composed of a white tough membranous bag, capable of holding about four pints, and a flattened round solid mass, the cells of which contained various matters from the consistence of pus to that of cerate, and of considerable variety in colour. The interstices of the cells were of a hard cartilaginous structure. Inside the large membranous bag, hung from its under surface a pendulous mass, with a narrow neck, about the size of a hen's egg, or rather larger, and of an irregular shape, very similar to a portion of brain enclosed in a thin transparent membrane, which must have floated loosely in the fluid of the sac. The tumour with the membranous bag had very much the appearance of a large placenta with its membranes nearly entire, and its form and arrangement exactly similar. On examining the membranous pouch very carefully, I could find no puncture but the one by which the sac had been emptied at the pedicle; and as its capacity was not more than for four or five pints of fluid, this together with the apparently thick unyielding character of the walls of the sac, convinced me that it had never held more than from four to five pints; consequently, the twenty-five pounds and-a-half of fluid previously discharged were decidedly that of ascites, in no way connected with the cyst, but produced by its pressure. The connection of the tumour anteriorly with the parietes was to a considerable extent, and remarkably firm, completely surrounding the umbilicus, including the remains of the umbilical chord; in cutting through it, the part was hard, as a piece of cartilage, and not easily divided; the fibrous bands, connecting the tumour, with the omentum, intestines, &c., were in many places two inches in length, and very strong, (no doubt of long standing); they were arranged in groups of three or four together, most of them about the thickness of thread, but one or two were broad and flat like narrow tapes. The solid portion (as well as the membranous cyst of the tumour) was beautifully injected with blood vessels, both internally and externally. As the contents of the sac were discharged at the conclusion of the operation, I had not an opportunity of ascertaining its peculiarities;

RECORD OF FIFTY-TWO HOURS AFTER OPERATION ON ELIZABETH BESWICK.

Operation, 4 o'Clock p.m. Oct. 7th, 1842. Friday.	8 o'Clock p.m.	11 o'clock p.m.—7 hours after operation.	5 o'clock a.m. Oct. 8th. 13 hours after.	11 o'clock a.m. 19 hours after.	4 o'clock p.m. 24 hours after.	10 o'clock p.m. 30 hours after.	5 o'clock a.m.—Oct. 9th 37 hours after.	10 o'clock, a.m. 24 hours after.	8 o'clock p.m. 52 hours after.

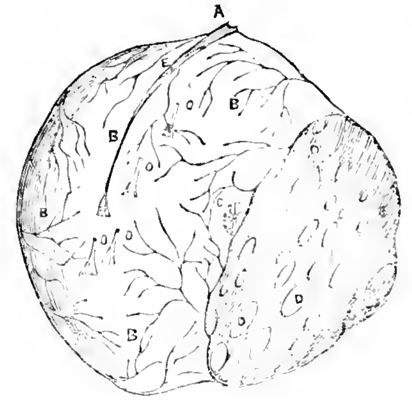
Cold........	None.	None.	None.	None.	None.	None.	None.	None.	None.
General Remarks. *The diet is to be understood as the same as in Mrs. Wheeler's case.*	There had not been the slightest coldness, or shivering.—The pain had left the loins and iliac regions.—Had slept soundly 20 minutes, and smoked a pipe of tobacco.—Pulse had risen.	Had had three sleeps, amounting to 45 minutes.—Pulse soft and compressible.—Felt as though she could pass her water naturally.	Her sleeps had been very sound.—Passed her water with great ease.—Pulse remained soft.—Took the panada and gruel well, and had smoked another pipe of tobacco.	Pulse very soft and compressible.—Has taken her diet freely.—Enjoyed her pipe, and felt perfectly free from pain.—Simple diet continued.	Expressed herself very comfortable.—Felt as though she would have a motion, and complained of being hungry.—No alteration in the diet.	For the first time felt a sensation of wind in the bowels.—In every other respect well.—Diet continued.—Gave her 10 grains of Inspissated Gall at bed-time.	Passed a very comfortable night.—Flatus not been felt since last night.—Diet continued.	Continues well.—Diet continued.	The tongue, for the first time, a little furred, accompanied with a little thirst and flatus.—Gave her five grains of Inspissated Gall.

The gross amount of matter removed was: ascitic fluid, 25½ lbs.—contents of cyst, 4 lbs.—cyst and solid substance, 5 lbs.—total, 34½ lbs.

SUMMARY OF THE FIRST FIFTY-TWO HOURS



AFTER OPERATION.

Before this, my second operation, I had concluded it scarcely possible that any case of such importance and peculiar liabilities could have progressed more favourably than in the case of Mrs. Wheeler; but, certainly, the present as far exceeded the first case, in the rapid progress of its recovery, as it did in having worse prospects to contend with in the beginning. The patient was older by many years, the system equally worn down, numerous adhesions of a very firm nature to overcome, together with an extensive ascitic deposit,—and yet it is impossible to look at the above tabulated 52 hours without surprise, when all these circumstances are considered.

The Temperature was kept nearly the same throughout, as in the first case, but in accomplishing this, fires had to be occasionally made as the weather was colder.

Pulse.—Before the operation the pulse stood at 70. After the operation it was counted by Dr. Radford, and found to be the same; a circumstance very remarkable, and only to be accounted for by the small quantity of blood lost during the operation, and the imperturbable coolness of my patient, who neither moved a muscle, nor expressed herself in the least as suffering from pain. During the fifty two hours it will be observed it advanced to 90, but always remained soft, and easily compressible, bleeding therefore was not resorted to, which, in consequence of her age, I was not sorry for.

Tongue.—During the time was clean and moist, except at the last visit on the table, when it showed itself slightly furred, probably owing to the bowels not being yet moved.

General Surface.—Was never otherwise than warm and moist, with gentle perspiration.

Pain.—For about half an hour the pain in the left iliac region continued, and also in the loins, but on giving three-fourths of a grain of mur. morphine it disappeared, and did not occur again.

Light Headedness.—Never occurred.

Cough.—There was not any.

Shivering.—None.

Urine. It was surprising how easily she passed urine by her own efforts, so early after the operation, and continued to do so throughout, amounting nearly to seven pounds in 52 hours; the catheter was, therefore, uncalled for.

Motions.—As yet none, but as flatus had troubled her a little towards the conclusion of the above table, a motion was expected.

Flatus.—Throughout was too trifling to dwell upon.

Respiration.—Never in the least disturbed.

Cold.—This sensation was never experienced even in the least degree.

Sleep.—The pain in the loins and left iliac region, rendered it necessary immediately after the operation to give three fourths of a grain of the mur. morphine The pain soon left and a sound sleep followed. The number of separate sleeps, their length, and soundness, amounting to upwards of seventeen hours in the fifty-two, no doubt facilitated much, her rapid and satisfactory recovery.

In the next table I shall dispense with those items of the last table which did not occur again, as pain, light-headedness, cough, shivering, flatus, respiration, cold.

All my medical friends who visited the case, were surprised at the progress of recovery, and the perfect absence of dangerous symptoms. The next table traces the case up to the first dressing of the wound on the fourth day.

GENERAL REMARKS.	Flatus	Sleep	Thirst	Motions . . .	Urine	General Surface . . .	Tongue . . .	Pulse	Temperature.	FROM THE CONCLUSION OF THE 1ST 52 HOURS, TO THE END OF THE 4TH DAY AND 1ST DRESSING.
Felt a little smarting and itching in the line of the wound—felt very hungry—diet continued.	None.	5 hours.	None.	None.	3 times ℥ii ℥xviij.	Moist & Warm.	Little furred.	90 Very soft	69	5 o'clock, a.m., Oct. 10th — 61 hours after operation.
Continued remarkably well—ordered a clyster of gruel, with olei ricini. olei terebinth, ā ā ℥ss, to be repeated if necessary.	None.	30 minutes.	None.	None.	Twice ℥xii.	Moist and warm.	Little furred.	90 Very soft.	68	12 a.m.—68 hours after.
Two copious motions followed the clysters—felt very hungry—no alteration in diet.	None.	12 hours	None.	2 after clyster.	3 times ℥ii ℥xviij.	Moist & warm.	Clean & moist.	90 Very soft	68	10 p.m.—78 hours after.
Had passed a very comfortable night—ordered a little weak mutton broth for dinner—diet, in other respects, as before.	None.	6 hours.	None.	None.	Twice ℥xii.	Moist and warm.	Clean and moist.	100 soft.	68	9 a.m., Oct. 11th—89 hours after.
Dressed the wound, removed every other suture—woundhealed its whole length except where the ligatures came out.	None.	None.	None.	None.	Twice ℥xii.	Moist and warm.	Clean and moist.	105 soft	68	12 a.m.—92 hours after.
The pulse, though high, was very soft, no pain or uneasiness—former diet continued without the broth.	None.	None.	None.	None.	Once ℥vi.	Moist & warm.	Clean & moist.	110 Very soft	68	5 p.m.—97 hours after.

(To be continued.

COURSE OF LECTURES ON THE THEORY AND PRACTICE OF MEDICINE.

Delivered by C. J. B. WILLIAMS, M.D., F.R.S., Professor of the Practice of Medicine, and of Clinical Medicine, at University College.

GENTLEMEN,—Lymph is very rarely thrown out upon mucous surfaces; pus is the secretion to which inflammation renders them peculiarly liable. It is on serous membranes that lymph is usually deposited, and although pus is sometimes found also on them, yet its occurrence is far less common than on mucous membranes. When lymph is of a *low* character, it bears a strong resemblance to *pus*, and is indeed, often a concomitant production. In these cases, the secretion is liquid, and presents a greenish appearance; it is called *purulent lymph*. The great facility with which pus is formed upon mucous surfaces, would lead us to expect that there must be considerable analogy between pus and the ordinary mucus that lubricates the mucous membrane; and this appears to be the fact, for it is in many instances, most difficult, and I may say impossible to distinguish clearly the two products. The former, viz. pus, passes gradually into mucus, which may indeed, be obtained from pus, by the addition of salt, an alkali, and some carbonic acid. Both are modifications of albuminous matter, and both contain a certain amount of fat. It is easy to discriminate between pus and mucus when in a *pure* state, the former being free from all viscidity, and readily miscible in water, while the latter is remarkable for viscidity and for its *not* being miscible with water. Pus is often found to be thrown out upon serous membranes when air has gained access to their cavities. The formation of pus frequently depends upon what is called the purulent *diathesis*. Many persons are accustomed to associate invariably with the existence of pus, a greater or less degree of *destruction* of parts; but this is an error, because pus may undoubtedly proceed from an *entire* surface without any *destruction* occurring. It is on this account very important to guard against concluding, that the lungs must necessarily be diseased because the sputa may contain traces of purulent secretion.

It was found by Hunter, that when pieces of flesh were placed in pus they became dissolved. It was concluded from this fact, that pus possesses a powerful solvent property; and that it consists, in fact, of portions of dissolved tissues, which it converts into itself; but the solution has been greatly exaggerated. Pus is *not* formed by conversion into itself, for it may, as I just stated, be effused from *entire* surfaces; it is in reality, a modified *secretion*. There is beyond all question frequently increased absorption, and removal of tissues adjoining the locality of pus; but then, this can be accounted for on other grounds than the solvent properties of pus itself, for example, *pressure* upon the surrounding parts giving rise to defective circulation, would be sufficient reason why cohesion should be diminished and the absorbent action be augmented. Sometimes the diminished cohesion precedes the formation of pus, and sometimes occurs alone, thus causing softening. Absorption on the surfaces of the body would be called ulceration. Ulceration signifies the removal of textures; and suppuration signifies the formation of pus. This formation takes place chiefly in the arterial portion of the capillaries; it is here also that granulations are formed and lymph is effused. The process of suppuration taking place in closed parts constitutes, as you know, abscess. Anything tending to localize inflammation, such as the application of foreign bodies, &c., tends to produce suppuration. Some have supposed that pus is formed in the blood, and escapes through the parietes of the vessels. I have never been able to detect this transition, nor do I think it at all reasonable. The greater the complexity of a mucous membrane, the greater as a general rule is its tendency to become softened.

Another phenomenon of inflammation is increased *heat*. It is well known that inflamed parts feel *hotter* than parts in their natural condition; this change of temperature is manifest, both to the sensation of the patient, as well as to the hand of the attendant. The question will arise, whether the increased heat is due to the greater quantity of blood determined to the part, or whether it is owing to some change effected in the blood itself? Erysipelatous limbs sometimes rise in temperature to 105 deg. Sometimes in inflammation, injury is done to the vessels permanently, and death of the tissues is produced, constituting *gangrene*. This state may arise,—1st. From destruction of the vessels, as by extreme cold—2d. From *pressure* by effused matter or other circumstances, as in Hernia and intussusception—3d. A depressed state of the circulation may cause gangrene, as where blisters have been applied in low fevers, especially when situated at a great distance from the heart. It may also arise where acupunctures have been used in cases of dropsy—4th. Obstructed arteries as from ossific deposit in their coats may cause gangrene. They may for a long time support the parts under ordinary circumstances, but if any state should arise requiring reaction for which determination of blood is necessary, it is clear that if the obstruction be so great as to prevent such determination taking place, the part will be unable to resist, and as a consequence, must die.—5th. Another cause of gangrene is congestion. This is proved by the sloughing of the back that so frequently occurs in long illnesses, where the recumbent posture has to be maintained.—6th. Local causes may also give rise to gangrene, as poison of serpents, punctured wounds, &c. But a part may die without actually becoming gangrenous. As soon as vitality is degraded by impeded circulation, the parts are acted upon by the vessels and removed. They cannot resist the absorbent action; there may, in this case, be no gangrene, but simply softening and removal.

Again, if the part dead is of small size there may be ulceration of such dead part *itself*; but if the part be of a large size, the ulcerative process takes place round the *edges* of the mass, and it becomes separated from the surrounding portions as a *slough*. Still there is no *gangrene* necessary; *it* implies *decomposition* and *putridity*. But if the mass is too large, and is not separated rapidly, it becomes decomposed and gangrene results; this change is greatly hastened by heat, moisture, and exposure to the air. The death of a part thus existing may be productive of most serious constitutional mischief, by the absorption of the decomposed and putrid matter by the surrounding vessels; this will give rise to the supervention of typhoid symptoms. If the system is strong the surrounding vessels become the seat of inflammation, attended by the effusion of lymph, which stops the progress of the injury, and thus a line of demarcation is established; the lymph thus effused blocks up the vessels, so that the communication between the part decomposing and the rest of the system is effectually interrupted. When a portion has become completely dead it is said to be sphacelated, and in this condition the blood therein contained is changed to a *black* colour. The chief characteristic of gangrene is the fetid exhalation.

The principal mischief attending inflammation appears to consist in the throwing out of nutritive matter in the wrong places, or in greater abundance than nature requires. I have now pointed out to you the leading facts with regard to the nature and local consequences of inflammation, and we shall proceed to notice some other circumstances connected with it in relation to its influence upon the system generally.

The *causes* of inflammation are mechanical, chemical, and vital irritants; these may be called *local* causes. An example is found in the case of a calculus in the kidney, which by the local irritation may give rise to the occurrence of inflammation. Again, an obstruction existing in the alimentary canal may, by the local injury effected, cause the supervention of inflammatory action. It usually happens that the local results are in proportion to the local causes; thus the *size* of the calculus and the *amount* of obstruction would materially influence the degree of the inflammation produced. When a local irritant has been operating for some time, the action of the heart

becomes excited in frequency and force, and this organ then reacts, and especially upon the part that is the seat of the inflammation—the circulation through the whole body becomes considerably augmented. It will be asked how the irritation is communicated to the heart? We must attribute its increased activity partly to its reaction after a state of collapse, and partly to irritation transmitted through the medium of the nerves. In persons of nervous temperament this action is observed to be strongest. But inflammation may be produced by other causes than those that are strictly local,—it may arise from *constitutional* causes. External cold and heat produce internal inflammation, by producing great constitutional disturbance, out of which arises the local mischief. The first symptoms that occur will probably be chilliness, loss of appetite, nausea, vomiting, constipation, and depression of all the functions; during this time congestion is forming in some internal part, and hence it is called the *congestive* stage: these symptoms may either precede or accompany local inflammation. In a few hours reaction takes place; the vessels transmit the heart's energy more powerfully in consequence of their dilatation, this reaction, or state of excitement following the depression, is called the *hot* stage of the fever, and it is during *this* stage that the local inflammation is usually developed—the excited heart backing, as it were, the circulation through the affected vessels. Again, we find an example of inflammation arising from a constitutional cause in the case of pneumonia following asphyxia: in this state you know that the lungs are greatly congested and their function interrupted:—now if reaction occurs during this congested condition, the congestion becomes converted into inflammation, and thus pneumonia is determined. This state of reaction operating through the whole system constitutes what is known as *inflammatory fever*, the most remarkable symptom of which appears to be the increase in the action of the heart: during the decline of inflammation the pulse becomes much softer, in consequence, of course, of the heart's action being diminished. A brief description of inflammatory fever would be *coldness and depression, followed by excitement and heat.* Not only is the action of the heart augmented, but the whole vascular system and its functions (secretion, absorption, &c.) are affected also, and sometimes to a very considerable and serious extent. We have abundant evidence of the derangement that is produced in the symptoms that present themselves: these are chiefly heat and dryness of the skin, nausea, restlessness, thirst, high-coloured and scanty urine, constipation, clamminess of the mouth, with an unpleasant taste and furred tongue: also loss of appetite and an arrest of the gastric secretion: so that if food were taken it would remain undigested in the stomach, and be productive of increased irritation. If any ulcers should be present upon the surface of the body their discharge is very frequently diminished during inflammatory fever, and it is even sometimes entirely stopped. In addition to the symptoms already stated are the affections of the *sensation*, which becomes morbidly increased in certain parts, causing uneasiness and pains; also, intolerance of light and sound, sparks flying before the eyes, and noises in the ears, constituting tinnitus aurium. The motor power is unsteady, and hence tremors are often present. The mental faculties are also weakened; and delirium is by no means uncommon. The increased heat is a constant feature, and is owing, in a great measure, to the diminution of the perspiration, although it does not at all necessarily follow that because perspiration is profuse great heat will not *also* exist. All the functions are not equally affected, although the whole circulation is increased. The arteries are in a state of great tonicity, implying rigidity of tube, and, therefore, the pulse is hard; it is in consequence of this rigidity that the secretions are diminished. The capillaries are contracted; this contraction was, as I have previously mentioned, ascribed by Cullen to spasmodic action. There is no evidence of spasm amounting to obstruction.

PRIVATE COURSE OF OPERATIVE SURGERY.

By J. NOTTINGHAM, Esq., Member of the Royal College of Surgeons of London.

LECTURE III.

To many of you, gentlemen, the taking up of a bistoury, and the making of a cut or incision, might appear to be what is called a very easy matter, requiring no great surgical skill or previous preparation. Such an idea, however, of this elementary part of surgery, should be immediately banished from your minds; for, in truth, the doctrine of incisions, if fully detailed, and in every part investigated as much as it deserves, would form a very considerable portion of the science of practical surgery.

I do not intend by this prefatory remark to persuade you that the study we now enter upon is fraught with any uncommon difficulty—it is, however, my wish that you should regard it as one of considerable importance, for it bears upon nearly all the surgical operations of a serious nature, so that the rules to be observed as relating to it, are of every day—of constant application.

The study of the incisions practised for the removal of limbs, will be deferred until we consider the subject of amputation; so that, at present, it is for the most part what might be called minor incisions of which we are about to speak.

Before the surgeon touches his patient with the point or edge of a cutting instrument, he should take care to place himself in a favourable position with regard to that part of his patient's body on which he is about to operate, so that he may neither feel, nor seem, awkward during the performance of that which has to be done; the operator should be satisfied, before-hand, that the sufferer cannot, or will not, start from the posture which has been chosen as best suited to the operation; and the former condition of this precaution should always be preferred to the latter, where children or undecided people are to be dealt with. In such cases, if one limb be the subject of operation, the other three may be confined in the folds of a sheet or long towel. Where any part of the face or neck is operated on, the child should be completely rolled in a strong sheet, or blanket, as the best means of preventing those sudden starts of the limbs, or writhings of the trunk, which may arrest or materially disturb the progress of delicate incisions. These precautions I have often found valuable during the hare-lip operation; and, also, in one case of the ligature of the common carotid artery, in a very young subject.

It is not often desirable to tie the patient hand and foot, except in the operation for stone; but security against starting should always be obtained in some way or other, wherever an incision is about to be made, except in cases of mere puncture, or where the sudden and momentary plunge of a lancet achieves all that is required.

If an operation consist of a simple incision, to be done at once, as with the bistoury, the preparation of the instrument is easy; but if it be so far complicated as to require many incisions, and the employment, perhaps, of more than one or two instruments, these should be ascertained by the surgeon himself, beforehand, to be in good order, the blades of knives clean and well-polished, their points sharp, their edges keen, and set in the right direction; the joints of scissors and forceps, moving easily and freely, without grating on the one hand, or over-slackness on the other, and their edges and points attuned to their office. Such instruments, during the operation, should be placed near to the surgeon, and, if possible, within his reach, that he may lay hold of those he requires, and thus render himself independent of lookers-on, who, to use the words of a great master of the art, in nine cases out of ten, owing to anxiety, or curiosity, hurry and agitation, hand any thing but what may at the instant be required.

The patient prepared—the instrument prepared—the surgeon prepared—the part to be operated upon must also be prepared, before the knife approach it. Where incisions are about to be extensive, the surface should be previously shaved, if the hair upon it would be likely to be troublesome during the operation, or in the future dressing of the wound.

The main consideration, however, connected with the preparation of the part, is that which regards the state of tension to be given to the structures we are about to divide. As much as possible, the surface to be divided should be rendered moderately tense by a circumferent traction, exercised equally in every direction; thus will the making of a clean cut be facilitated, and its terminations will be less likely to present the appearance to which the name "tails" has been given.

Often, however, the surgeon, with the fingers of his left hand pressing on the surface, opposes the traction exerted by the course of the knife in his right, without any lateral or cross tension being practised, which should, nevertheless, be obtained from the hands of an assistant in operations, where greater precision is required.

When dividing the integument over the situation of important blood-vessels or nerves, or parts which we are required to hit, or cut down upon, great care must be taken in stretching the skin, or practising the tension, that the surgeon, observing accurately the relation of any part of the integument to all which lies beneath, may not be misled when this is altered by the new position which stretching gives to the more superficial parts concerned in the operation; he should watch the motion imparted to the surface by his own fingers, or those of his assistants; and should take into account both its direction and extent; and should remember, at the same time, the peculiar extensibility or elasticity of the structure he is about to divide. This caution will be found more particularly worthy of notice in operations for the ligature of arteries, as the brachial, femoral, &c., while the neglect of it sometimes leads to no small confusion in seeking with the probe or scalpel, if such phrase may be allowed, the trunks of these important blood-vessels.

In making an ordinary straight incision with a common bistoury, an inclination is given to its edge, a little nearer to the horizon than that of the pen in writing; but at the commencement and termination of the line of incision, the instrument must be entered, and withdrawn, nearly in the perpendicular direction, that the different parts of the incision may be of equal depth, and its extremities well-defined.

The degree of force or pressure employed upon the bistoury, must depend on the depth of the incision to be made, or on the density of the parts to be divided.

Incisions may be said to be simple or compound, or straight or curved; for of the various combinations of the two latter, the others may be said to consist.

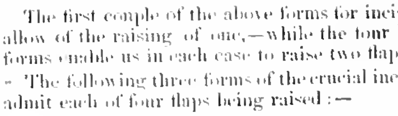
Incisions are often made to resemble, in their general outline, different letters of the Roman alphabet, the form of the following being more especially imitated:—

A V I C H L O T

The alphabet of incisions, however, is not confined to these, for figures like the following come in their turn:—

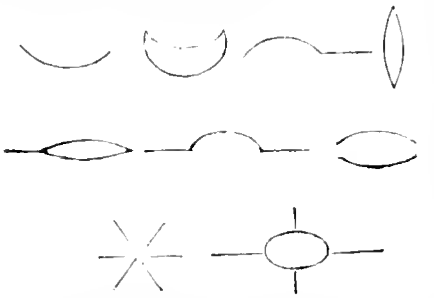
The first couple of the above forms for incisions, allow of the raising of one,—while the four latter forms enable us in each case to raise two flaps.

The following three forms of the crucial incision, admit each of four flaps being raised:—



It is better to keep as much as possible to straight lines, for, with the aid of these, reunion is more readily and more easily effected; nevertheless the shape, situation, or condition of deformed or diseased parts, oblige us now and then to deviate, not only from the straight line, but also, in

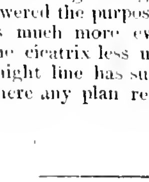
some degree, from any established rule. Hence the imitation of figures such as the following, in some operations of the bistoury:—



The two latter, especially the star-shape, can seldom be wanted; Malgaigne, however, has thought it worthy of notice, in his work on Operative Surgery; and the other may be required in exposing vascular growths, so as to surround them by ligature, where it may be necessary to remove part of the integument; and still further, to denude the subjacent structure, by the turning back of the flaps. Mr. Liston gives a representation of this incision in his valuable work on Practical Surgery, and speaks of having employed it in a case of subcutaneous erectile tumour on the shoulder of a child. Part of the integument was discoloured, and adherent to the subjacent mass, *nævus maternus*; but the boundaries of the tumour extended far beyond. In order to surround the diseased parts, it was found necessary to make the incisions as represented in the accompanying figure, and to dissect the intervening integument from the surface of the tumour, to the requisite extent.

Although the form of incisions be so much varied, the most simple are those which are most frequently employed, one straight line being required more frequently than any other kind of solution of continuity on the exterior of the body; for this varying in length, suffices in the majority of scarifications, in the opening of abscesses, in the removal of small tumours, in most of the operations for the ligature of arteries, and in some of those performed for the relief of strangulated hernia, in the operation for stone, &c.

There is one error which young surgeons are very apt to commit in cases, where much depends upon the situation and extent of this single straight incision. In many of the cases just now alluded to, we need not say any thing respecting the importance of choosing carefully the locality of the incision, or the line of surface through which it must pass; but let it be remembered, that in eight cases out of ten with ordinary operators, the first straight incision is made TOO SHORT, and thus every future step of the operation is rendered comparatively awkward and difficult, its progress retarded, and the sufferings of the patient increased, until the surgeon, perhaps taking a hint from the bystanders, extends his first incision, to give that facility to the rest of the operation, which he ought to have had from the beginning; but even this way of making the best of a bad job, is better than the plan, sometimes adopted, of changing the figure of the incision by giving to it a side branch, for the purpose of raising a couple of unnecessary flaps—where a little lengthening of the single line would have answered the purpose, for the reunion of the parts is much more even, more readily effected, and the cicatrix less unsightly, where a single and straight line has sufficed on the exterior, than where any plan represented by this figure



is resorted to.

There are but few instances where the external incisions now alluded to, need be confined within very narrow limits; and if they should be made half-an-inch too long, never mind, this can do no great harm,—but, if allowed to remain too short, the annoyance to the surgeon is great, and the injury to the patient may be equally so.

Some of the figures we have exhibited as representing forms of incision, suppose the removal of a portion of integument, a proceeding which should never be resorted to where we can avoid it; and, as far as tumours are concerned, this is not so often necessary as might at first be imagined,—and this fact, like many others connected with Operative Surgery, reminds us of the importance of attending to the peculiar vital and physical properties of the parts concerned in surgical operations; for the extensibility of the skin is very great, and, inasmuch as it possesses a corresponding contractile power, we shall find that after the removal of very large tumors, which have grown beneath it, the tegumentary membrane will gradually creep within its primitive limits: while the wrinkling in the neighbourhood of the cicatrix, which may at first look awkward, will afterwards by degrees disappear. By way of illustration, the following case may be mentioned, which occurred to me a few months ago.

A middle-aged man had a tumour of the neck, in front of the wind-pipe, of the shape of the human kidney, but larger; it had been some years in gradually attaining the size it had, when I first saw it. It was very unsightly, forming a large projection which prevented the approximation of the cravat to the fore-part of the neck: but its disagreeable aspect was its least inconvenience, for it pressed upon the trachea and larynx, and kept up a continued irritation about the glottis, and a very troublesome cough. Before the patient came under my care, he had rubbed mercurial ointment upon the tumour, and taken internal remedies for it at the same time, but without any good effect. On examination, I found that it did not consist in any enlargement of the thyroid body, but that it was an encysted tumour, with a tolerably strong capsule crossing the neck, the extremity of it on the right side being placed somewhat higher than that on the left. It was, in short, one of those large tumours of the neck which have been so carefully studied and well-described by a venerable and experienced surgeon, the late Sir Everard Home. On the exterior, its general aspect was rounded, the kidney shape coming more into view as the divided integument was pressed aside at the time of its removal.

A longitudinal incision was made over the fore-part of the tumour, which extended also above and below it, reaching from a point not far from the back of the chin, to within a short distance of the top of the sternum, the divided integument was drawn aside, and the tumour exposed by dissection; a strong thread being passed through it was given to an assistant, who by traction exerted upon it, rendered tense the different parts of the cellular tissue as they came beneath the touch of the knife; and in this way all the connections of the tumour were divided, and its removal in the entire state effected. The larynx was exposed, and the muscles lying upon it, and the beating of the right carotid could be very distinctly seen; and the chasm made beneath the uplifted skin was large enough, when the tumour was removed, to admit a small closed fist. Yet although such was the extent of the integument left, the line of wound healed as kindly as possible, and the skin has gradually assumed its natural condition with regard to extent. The man has long been perfectly well—freed from that disturbance of the respiratory apparatus from which he previously suffered—and the integument of the neck is at present in no way peculiarly wrinkled or redundant.

Mr. Liston has valuable remarks on this subject. He says:—"In all cases where the skin is not thinned to a great degree, and altered in structure, it will be prudent to leave nature to deal with it, when laid down in position, after the removal of the offending part. In such cases, however, great care must be observed as regards the approximation and retention of the edges, and the formation of a dependent opening, so as to prevent accumulation of blood, serum, or pus, at various periods of the cure."

The engraving accompanying will give some idea of the aspect of the above case, before operation, and of the value of the practice now recommended to notice.

ON THE LAWS OF THE DEVELOPMENT OF ORGANS; OR, TRANSCENDENTAL ANATOMY APPLIED TO PHYSIOLOGY.

By E. R. A. Serres, Member of the Institute, of the Academy of Medicine, Professor to the Museum of Natural History, Paris, &c., &c., &c.

Theory of homologues—Its application to the organisms of the invertebrata—Principle of the analogy of organic tissues, by Bichat—Origin of comparative Anatomy—Principle of the correlation of forms, by Cuvier—Geoffrey Saint Hilaire's theory of analogues—Comparative ovology—Theory of centripetal development—Transcendental anatomy, as compared with zoology and comparative anatomy.

I EXPLAINED to you in my last lecture, how Haller adopted the theory of evolutions, to gratify his favorite idea of centrifugal development and of the creative action of the heart. The development of vegetables, as compared to that of animals, was as a consequence forcibly excluded from this theory. The separation of the two kingdoms was the necessary effect of the tardy period at which these observations were commenced. The system of Aristotle and of Aquapendente, took precedence of that of Harvey and of Malpighi. Epigenesis, on the contrary, tracing matter in its passage from the inorganic state to that of organization, following it step by step through its various transformations, forms the true continuation of the system of Malpighi. As in the theory of evolutions, all analogy was rejected between the development of animals and that of vegetables, so is the study of this analogy one of the essential bases of epigenesis; here we find a common character in the works of Malpighi, of Needham, and of Wolf. These celebrated anatomists, however, fell each into a similar error; they did not confine themselves to direct observation. Attempting to soar still higher and endeavouring to explain the cause of the difference in development between vegetable and animal matter, their researches became imbued with a mixture of conjecture and of fact which not only impairs them, but frequently even renders them unintelligible.

From these combined efforts, however, sprung the science of organic evolutions, which, regarding the organisms at their secondary period of formation, is in reality but the study of the second stage of epigenesis. Setting out from this point, epigenesis and the theory of evolutions progress together, following the organic transformations up to their perfect development. We will, however, point out the differences between these two theories. That of evolutions commences only when the first formations are completed, that is to say, at the appearance of the heart. All that precedes this

stage, is considered to pre-exist or to be preformed. This unknown period, on the contrary, is the constant object of the labours of epigenesis, inasmuch as the laws of formation can only be appreciated before the formation of the organisms: or rather, during the progress of their first rudiments. Hence do we find in the theory of evolutions, a total absence of laws of formation: in that of epigenesis, on the contrary, a constant necessity of the study of those laws; in the theory of evolutions, a neglect of the relations which exist between vegetables and animals; in that of epigenesis, a necessity for their consideration; in the theory of evolutions, an increase by *intus-susception*; in that of epigenesis, an increase by *extra-susception*: in evolution, a development of organs by extension and by continuity; in epigenesis, a development of organs by the successive addition of homogeneous organic materials. While tracing the conversion of the theory of pre-existences into that of organic evolutions, we may also follow the transmission of the ideas of one period to another in anatomical researches; for we must remark, that the application of the same principles in science almost always produces similar results, modified simply by the progressive march of observation. Thus the principle of unity and of continuity of organisms had produced, as we have previously said, the theory of histologic homogeny; the same principle conducted, with the system of evolutions, to the theory of organic homology. In place of an elementary tissue, this was a collection of tissues, a compound organism which was presumed to give birth by its extension and by its repetition to all similar organisms.

André Bonn was the first who, in tracing the organisms one from another, remarked the repetition of the parts constituting them,: the hair, the nails, the teeth, the glandular follicles, being reduced to a common type, undoubtedly constitute a fact as remarkable as the transformation of the cutaneous covering into the mucous membrane, which first fixed the attention of anatomists. That which André Bonn had done with regard to the general covering of the organisms, Vicq-d'Azzr attempted in reference to the limbs of men and animals. The analogy between the upper and lower limbs is so evident that it has at all times struck even the common observer. But the anatomical demonstration of this vague idea required the whole power of a genius, such as that of the French anatomist. He compared bone with bone, muscle with muscle, and vessel with vessel. The result of this comparison was to show that the same parts are repeated exactly in the composition of the upper and lower extremities. Independently of this relation, there is also in the work of Vicq-d'Azzr the germ of the principle of co-existence and of harmony of parts, the demonstration of which constitutes one of the greatest glories of Cuvier.

Hitherto homology was merely, so to speak, of individual application. By comparing two organic elements, different in appearance, some analogy was shown in their composition; but no general element was possessed which served as a type, and from which all parts of the same organic system could be deduced. The trunk appeared eventually to furnish this element. Every one knows that the spinal column in man is formed by a succession of vertebræ placed one upon another. The spine is then in reality but a repetition of the vertebra. Now, the spine is surmounted by the cranium, and rests on the pelvis. What then are these latter parts? What are their relations with the chain of vertebræ which unites them together? The most original idea was, doubtless, that proposed towards the conclusion of the last century, and which regarded the cranium as a pure assemblage of vertebræ. Goethe appears to have been its author. But M. Duméril in France, and Oken in England, are the first who demonstrated this relation. The cranium is then a repetition of the vertebral column; and in the same manner, the sacrum is but its continuation. Thus limited, the doctrine of homologues does not appear liable to the objections which have been raised against it. But can the same be said of those propositions of MM. Oken and Spix, in which they attempt to trace in the different parts of the head the repetition of the various parts of the body—the thorax in the nose—the pelvis in the os hyoides—and the whole bony system of the limbs in the maxillæ and the teeth? or can we with M. Meckel consider the *glans penis or the clitoris*, as a repetition of the tongue, the vagina of the nasal fossæ, or the small bulb which terminates the spinal marrow as a repetition of the brain? Would not these forced analogies bring the organization of the vertebrata down to the level of that of the invertebrata? In the latter class of animals, the simplicity of the organisms justifies this repetition; it has moreover been placed beyond doubt by the researches of M. Savigny upon insects and the crustacea, and by those of MM. Dumal, Meckel, Audouin, and Duges, upon polypi and the annelida.

By the side of this unitarian anatomy appeared the general anatomy of Bichat. In opposition to histologic homogeny, this system might be denominated differential histology. Created under the influence of the theory of pre-existences and of evolutions, it took from physiology its principal direction, and with a view of unfolding the properties of organisms, it applied itself in an especial manner to the consideration of their structure.

This study necessarily brought back that of the tissues. The school of Haller had not neglected this subject: the osseous and muscular systems had been the object of the labours of Albinus, of Winslow, of Sabatier, &c.; the vascular system had especially occupied Ludwig; the lymphatic vessels, Cruikshank and Mascagni; the nervous system, Haller and Prochaska. Important discoveries had marked the course of these anatomists: but scattered and unconnected they remained unknown the one to the other. This defect, so sensibly felt, Bichat removed by his magnificent work on general anatomy.

Sufficient attention has not been paid to the means by which this grand work was created. It was not merely by the most able dissection, nor by the chemical re-agents to which the various tissues were subjected, nor even by the analysis which he made of their properties, that Bichat attained his end. These material processes were in reality but as the scaffolding to the building. A constantly prevailing idea governs over the rest; namely, the principle of the analogy of organic tissues. The anatomical characters of a tissue once laid down, Bichat traced this tissue through all its modifications and transformations, and did not abandon it until obliged to renounce his rigorous modes of investigation, which are the touchstone of the principle of analogies This it was that constituted his system of anatomy. Analogy of structure, analogy of properties, consequently analogy of functions; this is the characteristic distinction of the immortal work of Bichat and the source of his useful researches. While tracing the transition of tissues, with a view of studying their normal transformations, Bichat perceived that these transformations also take place in an abnormal manner. Now, this abnormal evolution of tissues by modifying them, in like manner modifies their properties, and by modifying their properties, inevitably induces a change in their functions: thus constituting disease. Hence, then, we trace disease to the transformations undergone by the organisms. Now, these transformations, called accidental, when considered in themselves and in their relations with functional modifications, give birth to a new science, pathological anatomy. It is this science, originated by Bonnet and by Morgagni, which was raised so high by the researches of Laënnec, of Bayle, of Corvisart, Dupuytren, Meckel, Andral, Louis, Breschet, and others. It is to the study of diseases what normal anatomy is to physiology. Thus do all the medical sciences form in the aggregate a chain linked together by the principle of analogies.

What are we in medicine, if not the disciples of Bichat, the followers of his views upon anatomy and of his ideas upon the correlation and the evolution of functions, so well laid down in his "*Traité de la vie et de la mort?*" Is it not by following the routes marked out by his genius, that medicine in France has attained the elevation on which it has been placed during the last half century? The progress of medicine has, in fact, depended on that of pathological anatomy; the latter on the advance of general anatomy; and general anatomy itself is lastly but a fruitful application of the principle of analogies. It is thus that comparative anatomy was originated. Daubenton was the first to comprehend the general principle, the common bond of all the separate facts which serve as its basis. He took man as the term of relation, and animals as means of comparison. He, for the first time, gave to this study a fixed direction, a course in which Vicq-d'Azyr afterwards laboured with such great success. But neither Vicq-d'Azyr nor Daubenton succeeded in giving it a truly scientific character; this glory was reserved for the illustrious Cuvier. It was not, however, by constant dissection, nor even by the most careful comparisons alone that this study became erected into a distinct science. This was accomplished under the influence of a principle, that of *the correlation of forms*. The organic forms in man and animals are made subordinate one to another to produce a fixed action; a given form necessitates a second, the second a third, the third a fourth, thus gradually connecting together the whole series of organisms from whence animality results. Considered in this way, comparative anatomy made rapid strides towards two grand results; on the one hand, it connected with the forms in man the variations of form in animals; and, on the other hand, it rendered subordinate one to another the forms of animals by establishing their reciprocal relations. From the first result sprung differential comparative anatomy; from the second arose zoology, the fundamental principle of which, deduced from the correlation of forms, was the *subordination of characters*.

We now come to the subject of animal fossils. These remains were known before the time of Cuvier; they were carefully treasured up in libraries, and written on in most of the academical memoirs; but not a single general idea had been emitted upon their minute descriptions. Cuvier appeared and applied to them the principle of the correlation of parts, already proved by comparative anatomy, and quickly these bones, leaping as it were, from the depth of their sepulture, rallied at the voice of this principle their scattered fragments, and arranged themselves in skeletons as complete as those prepared in the laboratories. This unexpected resurrection was not confined to the skeleton; lost animals reappeared before us, with the entire characters of their order and family—presenting a kind of image of the creation,—an example of the power of an idea, or of a general principle, even in the sciences depending on observation.

Here ended the reign of organic pre-existences; its last hour was naturally brought about by the decline of the grand discoveries, which the anatomy of organisms gave rise to in their perfect development. The principle of the correlation of forms and of the harmony of parts had been its grandest and most fertile result. This principle, being founded on the idea that the organs of an animal form an entire whole, of which all the parts hold together, acting and re-acting one upon another, it resulted that no modification could take place in any of these organs without producing corresponding and analogous results in all the others. Their harmony could only be conceived by means of this mutual and general agreement. The consequence of this principle, in organogeny, was not only to render prevalent the idea that the young embryos are the miniature of the perfect animal, but even to check in its development the theory of evolutions, according to which slight transformations are allowed to take place in the organisms. New principles then became requisite, to give to organogeny a fresh impulse and bring it back into a direction which it had abandoned; it was, moreover necessary that these principles should direct attention upon the order of facts transitorily presented by the organisms in the course of their development. These requisite principles were not long in appearing. By the side of the differential theory of organisms, arising from the principle of the harmony of parts, was erected the theory of analogues, springing, on its side, from the principle of organic analogies, so clearly arranged for the first time by Geoffroy St. Hilaire. The basis of this new theory was the principle of analogies, as that of the preceding was the principle of dif-

ferences; its object was to establish the analogy of composition in organs and in animals, in opposition to the differential theory which pre-supposed them essentially different. Now, for the purpose of establishing this difference, authors had merely pointed attention to the state of organs and of beings in the last term of their development. Geoffroy St. Hilaire, on the contrary, wishing to show their analogies, directed his study over the different periods of development in organs and in animals. It was thus that he most clearly demonstrated that before differing, animals and organs are originally analogous. For the fixity of organic forms and the invariable character of zoological species, consequences derived from the differential theory of organisms, he substituted their variableness, an equally logical deduction of the theory of analogues. Against the reasonings of the differential theory, he opposed powerful organogenic facts. Under the influence of the differential theory, comparative anatomy and zoology remained purely descriptive sciences, similar to that which in man is named descriptive anatomy; but guided by the theory of analogues, these sciences became as general as human anatomy under Bichat. Thus what Bichat had done for organic tissues, Geoffroy St. Hilaire performed for the organisms and development of organs. He sought in the embryogenic state of animals, analogies which afterwards become effaced by the series of developments; and thus opened to science a new path abounding in fertile results.

Whilst Geoffroy St. Hilaire was giving this new impulse to the study of organogeny, demonstrating by experiment that the organisms of the lower vertebrata are represented in a transient state by the organisms of the embryos of the superior vertebrata, M. Meckel, in Germany, was following up the theory of organic evolutions as promulgated by Haller; MM. Spix, Oken, Müller, de Blainville, &c., were generalizing the homologic views of Bonn and of Vicq d'Azyr, by calling to their aid the data furnished by the differential theory, as well as those resulting from the theory of organic analogies. Lastly, comparative ovology, almost abandoned since the time of Hunter, received from the labours of M. Dutrochet that active impulse which MM. Cuvier, Oken, and Carus, have so ably followed up.

Still, in the theory of analogues, as well as in that of evolutions, or in that of homologues, organogeny constituted but an accessory part; it was not considered as a distinct science. And this, notwithstanding the facts collected by Aristotle, Aquapendente, Harvey, Malpighi, Maitre-Jean, Haller, Needham, and Wolf. But the misfortune was, that these facts being used in their turn either to sustain or to combat those general ideas, of which we have been giving a sketch, being often interpreted in a sense inverse to their true manifestation, formed in their assemblage an inextricable chaos, in which the mind in vain sought for a rallying point. This rallying point, however, does exist in nature; for, on the one hand, embryogeny presents to us the organisms, in their primitive state, separated and disjointed; and on the other hand, in their complete development, the anatomist observes these same elements united and combined so as to form a regular and perfect whole. How, then, does this metamorphosis take place? Is it chance which presides over an order of development, so constant, so regular—an order which is even maintained in apparently irregular formations? How can such perfect order exist, unless these developments be subject to fixed and general rules? The existence of such rules had been at all times felt, although nothing precise had been arrived at on the subject. How, then, attain this so desired end, the constant object of the efforts of so many anatomists, except by the one sure road—that of observation? It is this method—the only safe one in the natural sciences, which has shown to us the primitive division of organisms, as well as the rules which they follow in their progress towards union. It is by observation alone that we have seen them sometimes running regularly through all the periods of formation assigned to them, at other times arrested in their progress, and thus producing infinite varieties of form, but always designed upon one common basis, and formed of analogous materials. It is observation, aided by comparison, which has discovered to us that the organisms of the inferior animals are arrested in their developments at one or other of the embryonic phases of the superior animals; and that the various periods of arrest undergone by the organisms of the superior embryos, produce those numerous and varied organic malformations which constitute, in a great part, the domain of pathological anatomy. It is, lastly, by observation, comparison, and reasoning, that, descending or ascending the chain of the animal kingdom and of its embryonic productions, we have been enabled to rally that multitude of facts under one general and common law—the centripetal law of development which governs them all. Thus is the theory of centripetal development but the realization of the epigenic formation of man and of animals, as imperfectly glanced at by Harvey, Needham, Wolf, and Haller himself, before he abandoned the now invincible cause of epigenesis.

Transcendental anatomy thus embraces within its scope the immense field of animal organization in a perfect state, and that still more extended one of organisms in the course of development, whether considered during the embryogenic state of the superior animals, or during the whole period of development of the lower orders of animals. The conditions which it includes are, thus, of two orders: in the one division, we have the transitory forms presented by the organisms in the course of their developments; and, in the other, the permanent forms or states at which the organisms are arrested in the lower animals. We thus arrive at the explanation of the perfect organisms by following the transformations which they undergo, at the same time taking into account their stages of arrest, whether normally in the inferior animals, or abnormally during the course of embryogeny in the superior animals. From the consideration of these individual facts, and from their comparison one with another, arise views and relations different from those presented by comparative anatomy and zoology, which are limited to the consideration of the organisms and of animals in a perfect state. As, in the natural sciences, distinctions are merely based on differences, so differential zoology and comparative anatomy, regarding essentially the distinction of animals and of their organisms, have necessarily made the study of differences the principal rule of their researches. The principle of the correlation of forms, and that of the subordination of characters, perfectly resumed the natural method of investigation and classification, which alone could conduct these sciences to their present improved condition. On the other hand, as in the natural sciences, we can only determine by analogies, so, analogy of function, that of form and of situation, that of relation and of connexion of the organisms, that of their formation and development, and that of the rules which preside over their association and harmonization, are the principal bases of the researches of transcendental anatomy. Their end is combination, as that of differential zoology and comparative anatomy is division.

But the differences and analogies of organisms do not exist simultaneously in animals. There is one period for analogies, and another for differences; the more that the former are effaced, so do the latter become more prominent. Now, the differences being well characterized only in perfect animals, or at the period when all the evolutions of their organisms are completed, it was especially and almost exclusively, to this period that zoology and comparative anatomy applied. Imperfect organisms were considered but digressions. Hence, these sciences experienced no check from the theory of pre-existence and pre-formation of organisms. Directed incessantly upon fixed and permanent forms, the variations which these forms had undergone in the course of their developments imported nothing. Epigenesis was totally neglected.

The analogies, on the contrary, being principally manifested in the course of these metamorphoses, it is to the study of the fugitive and transitory forms presented by the organisms during their transformations, that transcendental anatomy is especially directed. Regarding incessantly imperfect organisms, or those during the course of development, it naturally conducted to the consideration of similar organisms in the inferior animals; and meeting in them fixed forms, which become reproduced as transitory forms in the superior animals, it deduced from their comparison new laws and relations which bind them one to another. Thus did the chimera of preformations become replaced by the theory of epigenesis, as more conformable to organogeny and the successiveness of organs. We now see how transcendental anatomy became based upon general embrogeny, from the study of organisms in the progress of development; whilst zoology, and the comparative anatomy of animals, were founded upon the perfect organisms. This difference in origin was necessitated by the difference of results which these sciences propose to attain. The object of the one is the distinction of animals, while the other attempts their explanation. Transcendental anatomy ends where zoology and comparative anatomy begin.

But in placing organic metamorphoses upon this delicate foundation, we must avoid falling into error, by constantly adopting the most rigorous mode of investigation, and by proceeding from special to general facts. In the sciences of observation and experiment, a theory should be but the free expression of facts; it ought to form in its *ensemble*, a perfect syllogism, of which the facts constitute the premises, and the mutual relations of the facts, the consequences. But, while adopting this principle, we should not, as is too much the custom of the present age, fall into the opposite extreme. We should not, by confining ourselves to the simple inspection of phenomena, or the mere instinct of observation, reject, as suspicious, every general truth, and regard every abstract proposition as an error. It is not so much these abstract theories, as their abuses, which have retarded the progress of comparative organogeny; and this has arisen, on the one hand, from an ignorance of the various states traversed by the organisms in the course of their development; and, on the other, from an incorrect appreciation of the relations of these organisms throughout the animal scale. We must, then, to avoid error, study the different organs in their primitive state, that we may the more surely be enabled to determine the various conditions which they assume in their subsequent states.

PERISCOPE OF THE WEEK.

THE EXCITO-MOTORY SYSTEM.—Dr. Marshall Hall does not concur in the opinion that the grey matter is, in every instance, the source of power in the nervous system, whilst the white or fibrous performs the office of a conductor merely. There is one fact which refutes it entirely. If we sever a muscular nerve from its connection with the nervous centres, and irritate it by a needle or the forceps, the muscle or muscles to which it is distributed are excited into contraction. Now here is power, the excitor power. To say that the impression is conveyed along the nerve is to assert a fallacy; for the puncture, the pinch, is that impression, and this is not conveyed along the nerve. On the contrary, some power,—some *vis nervosa*,—is called into action, and this power does extend along the nerve to the muscle. Yet the nerve contains grey matter. In short, power is present, no grey matter is absent. This, therefore, appears to be an experimentum crucis. He adverts to another point, that of the part acted in walking by the excito-motory property and function. Too much had been attributed to the agency of this property in this case. The mind, it is true, might be fully engaged in other thoughts, or trains of thought during walking. But so it might during the performance of a piece of music. Yet each key of the piano was pressed down by a distinct act, not of the excito-motory power, but of volition. Nevertheless, as in the

celebrated case of the ostrich, the head of which was struck off by a crescentiform arrow by the Roman emperor, the contact of the sole of the foot with the ground, no doubt, did prove an excitant, and had its share in inducing the successive acts of the limbs in progression. It was essential, however, to the safety of the doctrine to restrain its application within just limits. The excito-motory doctrine by no means depended on anatomy. Physiology has its own facts, its own evidence, irrespective of those afforded by structure, which might, or might not, for the present, afford its corroboration of the doctrine founded on those facts. If we remove the head of a frog, for instance, and irritate a limb, movements are immediately induced. If we now remove the spinal marrow, these phenomena cease. Now these facts are solid, as if the terms grey and white matter had never been uttered by the human voice. On such facts the excito-motory doctrine is based. The doctrine has proved as stable as the stable basis on which it is founded. It is only necessary to restrain it within its own province. That province is extensive enough, both in relation to physiology and pathology; it embraces all the acts of ingestion and of egestion in the animal economy, acts never explained before, and the class of spasmodic diseases.—Dr. Hall thinks it particularly desirable that the term excito-motory system should be limited within the bounds which he himself has assigned to it, for otherwise objections might be raised which did not apply to his use of the term, but to the more and more extended use of that term by others. He had always limited the designations of "the excito-motory system," "the reflex action," &c., to the true spinal system, the system of the acts of ingestion and egestion, inclusively of the cerebral on the one hand, and the ganglionic on the other, and he would say that the members of the society should, for the sake of truth and accuracy, do the same. Besides, nothing can be more natural in itself, as well as essential to just views of the subject, than the divisions which he proposes. We may witness the phenomena of a perfect infant; the cerebral, the true spinal, the ganglionic functions, are all perfect. We may watch the phenomena of an encephalous fœtus; in this case the cerebral functions are entirely absent; there was no sensation, no voluntary motion; the true spinal and the ganglionic exist together, but alone; respiration is continued, but it wants the equability which is conferred by the cerebral influence; all the acts of ingestion and of egestion were performed well enough. Lastly, we may examine an amyelencephalous fœtus, that is, one without cerebrum, or the true spinal marrow; it is incapable of an extra-uterine life; not an act of ingestion or of egestion is accomplished; all is interior and ganglionic. If there is no other evidence of the distinctness of the three divisions of the nervous system, these facts, though but as it were *lusus naturæ*, would be sufficient. Let us not proceed to confound them again, either by including in the excito-motory system phenomena which in reality belong to the cerebral on the one hand, or to the ganglionic on the other. It will be easy to devise other terms if we wish to speak of either of these. In the same manner he observes, that the question of the respective offices of the grey and white matters of the nervous system have nothing to do with the doctrine of the excito-motory system, which was established on its own basis, that of experiment and physiology. Dr. Hall thinks these respective functions not yet made out. They exist undoubtedly, but they have not been shown to be the seat and the conductor of power respectively. The experiment of irritation of a muscular nerve, isolated from the cerebrum and spinal marrow, but in connection with its muscles, he has already adduced as the experimentum crucis; there was power but no grey matter. For to say that the nerve conducts the impression is illogical and untrue; the impression is a puncture, or a pinch, according as a needle or the forceps may be used. Is this conveyed? Is the puncture, is the pinch, conveyed? To give either another name, that of the impression, for example, and to say that this is conveyed by the nerve, is a piece of self-deception, illogical, and untrue. No. Nothing is "*conveyed*." But the *power*, the *vis nervosa*, the inscrutable nervous power, unknown, except in its effects, is *excited*; and this excitement is extended, like the power of an electric conductor, or of a galvanic wire, to use a vague analogy, to the muscle or muscles, which it excites into contraction. In fine, thus we have nervous power without grey matter. The merit, continues Dr. H., which I would claim especially for the true spinal system (so I prefer to term and consider it) is its practicability. It has been justly asserted by Dr. Sharpey that we cannot now pass along the wards of an hospital without being continually called upon to apply our knowledge of this system to the cases before us. Do we witness a case of apoplexy, or of injury of the brain, or of hydrocephalus? Do we witness the sinking of the vital powers in typhoid fever, or exhaustion? Do we require a diagnosis between cerebral and spinal disease? A knowledge of this system has become as it were our stethoscope, and it is by its means alone that we can proceed in our clinical inquiries. But this day I have witnessed a case of epilepsy, succeeding to hemiplegic symptoms. The disease is no longer confined to the brain; its influence is extended to the spinal system. How could we trace the course of this terrific malady without a knowledge of the latter system? Every day the question comes before one, Is the case cerebral or spinal? Is it one of the nervous centre, or is it one of incident nerves? &c. &c.

TO CORRESPONDENTS.

X.—*We pray to be excused.*

W. T. M.—*Our Correspondent, whose initials we give, and whose respectable name we have, asks if he take the trouble to examine into Mesmerism, and "shew up its fabrications," whether we will allow him space in* "The Medical Times," *for the purpose of publishing his Evidence.—Answer. Cheerfully. We published in a number of vol. 5, a French Physician's statement on Calixte's* clairvoyance, *which he attributed, after much examination, he said, to trickery. Mesmerism, whatever it* is, *certainly* ought *not to be an affair of partizanship. As importantly connected, either by pretension or fact, with medical science, it calls for enquiry, and has a title to* fair play. *We should be very sorry to see it get more. We would not be accessaries to its getting less. We ask especially for* inquiry, *believing that as public journalists, it is our duty to favour the most searching investigations into this subject.*

Probe's Pencillings *of Dr. Roe (concluded) Dr. Bevan, Mr. Lyon, and Mr. Hale Thompson, in our next.*

A number of letters have been received.

We must postpone notice of a further mass of communications till our next number.

THE MEDICAL TIMES.

SATURDAY, NOVEMBER 5, 1842.

Non tua te moveant, sed publica vota.

MR. MACKINNON'S BILL—an abstract of which we gave a short time since—is good or bad, as we look at it in its *destructive* or *reparative* aspects. The evil of intramural sepulture is one of enormous magnitude. No powers of invention can exaggerate, as no powers of sophistry or impudence can extenuate it. Mr. Mackinnon has evidently reached this salutary conviction, and we must congratulate him that, relying on the good sense of the English people, he has dealt with the evil in a spirit of boldness, which, in these days of legislatorial timidity, argues well at once for the honesty of the promoter, and the eventual success of the measure.

The first clause of his bill, giving a home blow at the worst part of the system, annihilates all interments in churches, chapels, and private houses. A host of human carrion-mongers will, of course, rise in arms against an enactment of such inestimable value to the living. We shall, of course, be told of air-tight coffins, spacious catacombs, expensively-built vaults, newly-imagined and newly-erected crypts. Our answer is short. It is an abomination to have the dead mingling with the living. The human imagination, the moral sense—acting the forewarner against the physical evil—instinctively revolts against association with the decomposed and affrighting remains of what were once like ourselves. There is something horrible, something debasing, something *vulgarizing*, something demoralizing in the contact—the prospect—nay, the idea. With this—the positive corruption taints the air we breathe—makes rank the earth we stand on—incorporates its uncleanness in the waters we drink---it breeds disgust—it excites fear—it impairs, *destroys*, health—it poisons, tortures, *kills!* To change this may be ill to you—it is good for society. We cannot for ever shock decency, offend taste, destroy health, lower the tone of public delicacy and morals, to secure you a profitable traffic in human flesh—in plague-breeding corruption! The name of religion is defiled, not served, by connection with you; and this clause, carried, will do her more service than thousands received in burial-fees. It will allow churches and chapels to be attended with safety. At present, the wages, not of sin, but of piety, is *death!*

The next clause, enacting that there shall be no interments within a certain distance of cities, towns, and boroughs, forms with this, the *destructive* part of the bill, what (in some ignorance of the meaning of words in a *parliamentary* sense) *we* would call the *principle* of the bill. So far, Mr. Mackinnon has our enthusiastic support. He has shaped into enactments, improvements that the country is yearning after—improvements which advancing civilization has been demanding for years, with a constantly increasing importunity and power.

Let us now look at the honourable member as a legislative *architect*, in which character—it strikes us—another Mackinnon may follow him with advantage, and find alas! plenty to repair. He proposes, for example, on one side, that no cemetery shall be built within the fifth of a mile of a *gentleman's* house or *grounds*, without the owner's consent; he proposes, on another,

that a certain portion of the grave-soil shall be partitioned off exclusively for the poor, that no chance acquaintanceship may arise between pauper and genteel dust. We will not stop to enquire if these things were of *indispensible* enactment in his legislative bill—or of equal-handed justice in his legislative imagination,—but shall pass directly to consider the constitution of his Boards of Health. These he proposes to form in every parish and to compose them of three persons, the parson and the churchwardens! A committee of health without a medical man on it, Mr. Mackinnon? Are you serious?—for, if so, the manager who acted Shakespeare's Prince of Denmark *without Hamlet*, was a joke to you. Truly, if one were to form one's notion of medical men from their treatment by the House of Commons, we should really conclude that the only use recognized for them by the assembled wisdom of the nation, was, to be insulted *ad libitum*. What, surely are we good for, if not to be consulted on matters that concern health? If we are not at least as well qualified for the duty as the respectable parson, or the honest churchwarden, the sooner the State indemnifies us for the expences of our education, and prohibits the ceremony of our practice, the better. But so it is,—if ever there be a bit of patronage on the wing through the House, it may come ticketed with compliments to the clerical gentlemen, the bar gentlemen, the army gentlemen, the gentlemen about town—but never, by any chance, can it come to the unfortunate medical gentlemen. The nomination of barristers to overlook Lunacy Hospitals, and our omission here by Mr. Mackinnon, on Boards of *Health*, are happy illustrations!

If so good a thing is to be formed as General Boards of Health, why should Mr. M. neglect the machinery offered by the existing Boards of Guardians? If, for all matters concerning public health, the medical officers of the Unions, with the two oldest practitioners in the districts, were added as *ex-officio* members to the Boards, we should have bodies for the administration of the new Act which, if not the best, perhaps, that can be imagined, would be, at all events, far preferable to such petty nuclei of suspicion—of narrow-mindedness—of whimsicality—of interestedness, as are contemplated in the hon. member's scheme before us.

Mr. Mackinnon proposes, after five years, to give vestries full power to dispose of all grave-yards, private or public, in any way they may think fit. Is this just to the owners, or to the public? Is it shewing a legislative care of the general health, to place these open spots in the centre of large towns and cities, which, in a few years, might be made to atone for their past mischiefs to the public, by being made oäses in the city desert—ornamental promenades—places of exercise for the young—media of ventilation to all;—is it wise to place these at the mercy of the parochial parson, and two churchwardens? men who, from their habits, may often not be the most competent to judge, and, by their personal positions, often not the most disinterested in deciding, what may be the best attraction of such valuable sites.

The clause for *securing* early interment of the dead, though somewhat intermeddling, we look on with a favourable, though, in its present form, not with a *satisfied* eye. There can be little doubt that disease is much matured and spread by the too-common custom of keeping corpses in houses in a state of decomposition. An error on the other side is, the facility of premature interments—and we own that the possibility of so horrible a calamity operates upon us sufficiently strongly to make our support of the clause, useful as it is, contingent on the co-enactment of a body of medical police, who may watch over its administration.

Our praise, then, of Mr. Mackinnon's bill, can only be modified. It is too much for a prudent law—it is too little for a grand law. We question if his best policy would not have been, to have contented himself with removing the nuisance. In a healthy state of society, the removal of a peccant mass is the signal for the uprise of the more perfect substitute. A civilized country in anarchy to-day, will, by native force, find itself in order to-morrow: and if Mr. Mackinnon had closed burial-places in the town, he would not have wanted plenty of speculators to supply them for him in the country. Mr. Mackinnon, for a comparatively weak man, is a bold one: he has not only dared the enemies his bill required him to dare, but has thrown down the gauntlet to hosts of men who are far from being naturally opposed to him. We trust that the success of his battle with the worse opponents, will not be compromised by this superfluous extension of his hostilities. To prevent so lamentable a result, we suggest—and his *friends* will join in suggesting with us—that the bill of last year, may *not* be the bill of next.

He that chasteneth one, amendeth many.

English Proverb.

Ecce iterum Crispinus! Dr. Robert Hull is again at large! At the very moment we were congratulating our modern Quixote on a lucid interval, he was on the point of stalking abroad—the moon was at its full—to renew his fearful combat with the Windmill-Reform, and repeat his desperate onslaught on Common Sense and English Grammar. As, fortunately, he is his own Cervantes, and has for his Sancho Panza the Gazette's editor, we are favoured with a full record, in print, of all his sayings and doings in this (if he have friends) *last* adventure of his.

The chief feats of the present enterprize are in connection with the hospital physician, whom—like his rueful counterpart, shielding the boy from his savage master—he half-murders by the calamity of his protection. Dr. Hull proves the imperativeness of defining the character of the hospital physician. We pray he may be heard:—

The licentiousness of *reform*, which has distressed, *nearly subverted*, the empire, has *ramified* into our once *concordant* art; and unless the eyes of *its* professors are opened, will vitally damage *its* benefits. *I say* benefits, for, after all, the public are chiefly to be respected, when we discuss the *novel amalgamation of departments;* and I declare, with a venerated physician of the west, 'to me, personally, this will be of no consequence.'"

Perhaps our readers will think this a rather novel amalgamation of words. Certainly, there needs more intelligence than we can muster to grasp their meaning. They are psychological phenomena which, mystic as the mutterings of inspiration or idiocy, offer no chance of explication if he that spoke them, speak not again. Aristotle tells us---we should quote him in Greek if our readers were all as Hellenic as Hull—nullum magnum ingenium sine dementiæ mixturâ. If the latter admixture holds any fixed proportion to the former, the genius of Dr. Hull must be marvellously great. Something akin is obviously required to comprehend him. Warmed with admiration, let us pass from our own reflections, again to hear his:—

The division of labour is too sparing, not too *multiplicious*. This is shown in the metropolis, where full and successful play is given to the *divisional* arrangements. See the varieties of excellence in the same body of physicians: one intelligent *of* cerebral disorders; another *heartily* devoted to cardiac; a third *inspired* with *pulmonic* pursuits; a fourth *near dying* from investigations *of* the liver: all, authorities in their peculiar departments! So in the *surgic* arena: the herniotomist—the lithotomist—the amputator—the pathologist—*good* for joint-*evil!* Promiscuous labour cannot, logically nor consistently, step within the boundaries of a particular craft *nor* profession. If a man deserve those sneers which have been expressed towards him from a London chair, because he does not impudently pretend to universality in medicine, he is likewise contemptible because he does not expatiate, genius-like, beyond it Crichtonian perfection implies a circle of sciences. *The Duke* should unite, in his own person, the delivery of the nation and that of the Queen! and Dr. Locock is no philosopher, unless he can extricate an army from peril as well as a royal infant from *straits!*

—Or a Dr. Hull from a straight jacket, we had almost said, in our fears, that such merit as the writer's was beyond mortal appreciation.

Dr. Hull is fond of negatives: he uses them on the same principle, we suppose, on which he apparently uses his arguments—to destroy one another. What a pity we have not another Dr. Hull! The two negatives—positive negatives, by the way—would be invaluable to each other.

The doctor, after taking much trouble to establish the *imperiousness* of defining the character of the hospital physician, singularly omits to give us the necessitated definition. Will he allow us briefly to repair his oversight?

The hospital physician is frequently—we cannot, fortunately, say always, though, under the present system, he might always

he—a gentleman who had not, has not, never will have, one qualification for his post. Medical education and honesty, the two main attributes of every good physician, may have had nothing to do with his appointment to his office, and frequently have nothing to do with the discharge of his office duties. His position proves him to be a man of some wealth, or some interest—whether the first was acquired with honesty, or the second supported without servility, are things by no means matters of obvious, or even probable, deduction. Sometimes it may happen that he is a mere muddy-brained, grandiloquent pedant, who thinks himself profound when involved in a perplexity—witty, when laughed at, or a little extra-foolish---clever, when an object of wonder—as loved, because an object of solicitude; whose arrogance is equalled by his inanity---whose pedantry is surpassed by his ignorance---who explains the inexplicable by words that nobody before heard of, and elaborates illimitable *nonsense* into epistles of interminable length, which have no claim on human charity or endurance, save on the probable supposition that they are the *egesta* of a brain in a state of overcharged insanity!

All men, we are told, are fools *or* physicians at forty—never, surely, did man take so much trouble to prove that some may be *both* at fifty!

GORE'S AMMONIACAL SOLUTION OF ERGOT OF RYE.

(To the Editor of the "Medical Times.")

Dear Sir,—Having read in your valuable journal, some observations from Dr. Ridout upon the inconvenience as to time, of the *decoction* of ergot of rye, I beg to make the following remarks upon a form of that remedy which I have been using for several years, and upon the cases where its use is called for.

The "secale cornutum," is of such vast importance in the hands of the judicious accoucheur that any mode of preserving its qualities or of increasing its power cannot but be useful.

The tendency of the rye itself to deteriorate or get totally useless, if exposed to damp, and the frequent failures which appear to have resulted from the use of this remedy either in powder or the common tincture, long since induced me to devise a means of alleviating these evils. The preparation to which I refer, has, as far as my experience goes, during the past ten years accomplished every desirable end. I have had, during that period, the sole management of an "Institution for attending poor Lying-in Women at their own homes in cases of difficulty," upon the plan of the "Dublin Wellesley Female Institution," formerly conducted by Dr. Cusack, which has afforded me very many opportunities of observing the effects of the remedy; and I have heretofore declined publishing either the nature of the preparation, or the advantages attachable to it, until I felt quite convinced that both were worthy of consideration; and the *form of remedy* suitable for general adoption.

MODE OF PREPARATION.

Into half-a-pint of aromatic spirits of ammonia, I put four ounces of fresh ergot of rye, bruised coarsely. I allow this to stand for a month, frequently stirring the ingredient with a glass rod in the fluid; after which I squeeze every drop of the spirit out of the rye. The "ammoniacal solution," thus made, has a fine dark colour, and looks inspissated. In a glass stoppered bottle it may be preserved for any length of time without deterioration of power. This solution contains all the active principles of the rye in a convenient form, and increased efficacy, the ammonia causing the ergot to act more rapidly, and with greater certainty.

I administer 30 drops of it in a wine-glass of cold water, every ten minutes until the action required is sufficiently developed, applying gentle pressure with the flat of the hand, to the abdomen when the pains are present. Three such doses have, in the majority of cases which came under my observation, proved sufficient; but circumstances will now and then alter the requirements, as in other branches of medical practice in respect to various remedies.

It requires some consideration to determine the form of cases in which ergot of rye or any preparation of it may be used with safety and advantage; otherwise, the good expected, may be superseded by injurious results.

It is admitted by all who have had sufficient opportunities of using the rye *in its proper place*, that it is an invaluable addition to medical aid in such forms of difficult parturition; and that when it does act, varied degrees of contraction of the uterine fibre is the *specific* result of its administration, in cases varying in their circumstances.

Its use is therefore indicated in cases where inactivity or relaxation of the uterus is the *only* cause of delay; and where the uterine fibre has been stretched beyond the point necessary for its assumption of contractility. The full period of gestation having arrived, and the pains indicating the object which nature, apparently in vain, seeks to accomplish. It is necessary however, that other conditions co-exist before the remedy be employed; namely a *relaxed state of the os uteri, and of the other parts through which the fœtus has to pass.* In *such cases* as these if labour be protracted so as to cause anxiety, or justify interference, the ammoniacal solution of the ergot of rye will accomplish what is sought after without other aid than that required in ordinary cases of natural labour.

The indications for its use then are present when the propelling power is defective, or of itself insufficient; resistance to the fœtus from rigidity of the os uteri being no cause of delay, or only such as the induced uterine action is capable of overcoming.

In many cases, however, the head may be brought safely into the pelvis within convenient reach of the short forceps by this remedy, which advance alone is of very considerable importance: and in cases where the uterus does not contract with sufficient rapidity or to the necessary extent after delivery to prevent hæmorrhage, it proves of invaluable advantage: in such cases, however, circumstances demand more immediate collateral aid.

The conditions I have above detailed, will lead the practical observer to perceive, that in cases where the ergot of rye is indicated, the existing relaxation is that which frequently causes subsequent flooding, to supersede which, any means must be correspondingly natural. It becomes, therefore, apparent that the *remote* effects are as valuable where flooding would otherwise occur, as its *immediate* operation.

The state of relaxation where ergot of rye can be used with prudence, is almost always as *general*, as it is *local*; and in such conditions, the "aromatic spirit of ammonia," is not only admissible, but useful, so that the combination is unobjectionable as far as the latter vehicle is concerned.

Lastly, I have to observe that the cases in which we are called to administer ergot of rye, are the *very reverse of these* in which belladonna, tartrate of antimony, bleeding, and warm applications should be resorted to.—I am, sir, with many obligations for your kind insertion of this communication, yours very truly

W. R. Gore, M.R.C.S.

10, Cecil Street, Limerick, Ireland

Medical attendant to the "Limerick Institution for attending poor Lying-in Women, at their own homes in cases of difficulty," and to that "for the investigation and treatment of Diseases of the Chest."

Coronership.—The death of Mr. Smith, an attorney, leaves a vacancy in the coronership of the Southern Division of Staffordshire.—Dr. I. Turnbull, Dr. Dehane, of Wolverhampton, are among the candidates.

HYDROCELE COMPLICATED WITH HERNIA-HUMORALIS, CURED WITHOUT INCISION OF THE SCROTUM.

167, Bishopsgate Without, 1st November, 1842.

(To the Editor of the "Medical Times.")

Sir,—The following case which occurred to me at Rio de Janeiro, in the beginning of 1840, during my residence there, I beg to transmit to you, and hope, that if you think there is anything new or interesting in the treatment thereof, it may receive a place in your valuable and widely circulated periodical. I am, Sir, your humble, and Obedient Servant,

William Smith.
Surgeon.

Mr. F. W. a native of Great Britain, an apothecary, at Rio de Janeiro, presented himself to me in that city, in January, 1840. He was about 22 years of age, and had never laboured under any disease of the generative organs, save the one for which he now sought relief. His habits were regular, and his constitution good. On examining the scrotum, I found it swollen to four or five times its normal size; and by manipulation, I discovered that the left testicle was enlarged and hard, so as to increase greatly that side of the scrotum, in which it is situated.

Observing a lengthened cicatrix in the anterior part of the scrotum of the same side, my patient informed me, that he had been operated upon for hydrocele by a Brazilian surgeon about 18 months previously; which operation was performed by making a perpendicular incision of about an inch and a half long, dividing the scrotum and subjacent coverings of the testicle, until the cavity of the tunica vaginalis was exposed. The fluid of course escaped without difficulty, and a piece of India rubber bougie was inserted in the cavity, in contact with the testicle, having one of its extremities protruding at the wound. In this manner the external wound was closed around the foreign body, and the same treatment persevered in for three weeks: at the end of which time the bougie was withdrawn, and the wound thoroughly closed. The consequences of this treatment had been, painful swelling and enlargement of the testicle, which, at the time I saw it, was stated to be increasing, rather than diminishing; the cavity of the tunica vaginalis from this treatment, seemed to be quite obliterated; and fluctuation at no point of its extent was perceptible. Since the cure of the hydrocele had been in the above manner performed, the cavity of the tunica vaginalis of the opposite side had gradually been distended with serum; so that it surpassed in size the other side of the scrotum in which the swollen testicle was located. The patient had little or no pain on the side of the hydrocele; whilst the uneasiness of the other was very troublesome. He had been under the necessity of wearing a suspensory bandage ever since he had been operated upon; and the weight and size of the scrotum and its contents were daily increasing.

On ascertaining satisfactorily the seat and nature of the disease, I proposed to puncture the scrotum on the hydrocelic side with the trocar, withdraw the fluid, and inject a stimulating mixture of spirit and water, to excite adhesive inflammation. To this proceeding he objected, on account of the pain which he suffered consequent on the former operation, which had not even at this time altogether ceased; and thus I was under the necessity of trying the effects of local applications. Finding all the corporeal functions healthy, I ordered no constitutional remedies: but as a local application—Emp. Hyd. ℥iv. Pulv. Camph. ʒi, Misce bene et ft. Emp. This was spread on common lint, and so cut that it lined the inside of the net bag of the suspensory bandage, and I ordered the application to be renewed every third day. At the end of six days, my patient returned complaining of great pain of the scrotum; and, on examination, I found the cuticle pretty well peeled off from the whole surface which had been in contact with the dressing. At the same time the scrotum seemed much more swollen than before, and the dressing had been kept moist for the last three days by the serous discharge emanating from the surface. On the patient stating that he should be unable to apply the same treatment longer, unless he should confine

himself to his room, I changed it for that of Cerat. Calaminæ, to be applied in a similar manner, and changed twice a day. At the end of one week from this time, I found the surface healed, the swelling of the substance of the scrotum, which had been caused by the previous treatment, gone, and the quantity of fluid in the hydrocele apparently lessened, while the opposite testicle also seemed to be somewhat less bulky. Encouraged by these appearances, I applied the original plaster in a similar manner to the scrotum, which after being continued for eight or nine days, did not produce much irritation of the surface, while the fluid in the tunica vaginalis decreased more and more, and the testicle of the opposite side favourably diminished in size. This treatment was persevered in for three weeks longer; at the end of which time the whole fluid had been absorbed, and the swollen testicle exceeded the size of the healthy one, only in a very slight degree.

TWO CASES OF "FITS," WITH REMARKS.

By C. J. B. Aldis, M.D., Physician to the London Dispensary, and Lecturer on Medicine at the Charlotte Street School.

(For the 'Medical Times.')

Case 1. I was requested to visit Martha B., æt. 16, Sept. 29th last, residing in Hunt Street, by her mother, who stated that her daughter was in a fit, and had been so since two o'clock in the morning, and that she had suffered from a fit some time before, for which she was bled. I went immediately from the Dispensary, between twelve and 1 o'clock, and found the girl in bed, apparently insensible, and closely watched by her grandmother, who said that the patient had not spoken since two o'clock, although they had tried to make her sensible in every way they could think of. Pulse natural; skin warm; bowels said to be costive; catamenia regular. I called loudly to her, but received no reply; she seemed to be in a complete state of stupor. On trying to raise the eyelids, in order to examine the condition of the pupils, I found that she endeavoured to close them again. Suspecting the case to be hysterical, I told the mother to bring me a jug of cold water, and threatened to throw it over her if she did not return an answer to my questions. She had previously experienced a sensation of choking in the throat at different times. When the water was brought to me, I renewed the threat, and observed the eyelids begin to move. I was about to pour the water over her head, when she sat up in the bed, without opening her eyes, or returning an answer to my questions. On repeating the threat, she opened her eyes, and began to speak, to the astonishment of her anxious and wearied relatives. Aperients and antispasmodics, with cold affusion, every morning, were ordered. I told her to visit me at the Dispensary on the following Monday, which she did, and is now quite recovered.

Case 2. The following case is of a more serious nature, which occurred Oct. 24th, inst. The mother of the girl applied to me at the Dispensary to visit Sarah P. æt. 12½ residing in the Horse-ride, who, she said, had not spoken since 9 o'clock the same morning. I went immediately, between twelve and one o'clock, and found the patient lying in bed in a fit. Pulse oppressed; skin cool; bowels open; urine free; head warm; lips livid; foaming at the mouth; stertorous breathing. The pupils were contracted at first; but afterwards became dilated; feet cold; arms contracted across the chest; mouth firmly closed from rigid contraction of the muscles. Previously to her being attacked at 9 o'clock, she asked her mother for some meat, which was refused. Soon after the mother observed "a working of the fingers," and coma supervened. She had pursued her occupation of fancy trimming until Saturday evening, felt poorly on Sunday, and went to bed. Nine years previously she was attacked by measles, since which time she has been subject to occasional attacks of "asthma," according to the statement of her mother. Never had a fit before. Mustard poultices were applied to the feet, cold water to the head, and blood was taken by Mr. Gayton, the apothecary to the Dispensary.

After the abstraction of blood, the muscles of the mouth relaxed sufficiently to allow me to administer an active purgative, a portion of which returned through the nostrils, and the mouth became again firmly fixed. Various means were resorted to with a view to restore her, but she died in four hours afterwards. The permission of the parents having been obtained, her body was examined the next day. The mouth was firmly closed, and the abdominal muscles were very hard and rigid.

Head.—On opening the longitudinal sinus much dark fluid blood escaped. On removing the dura mater the surface of the brain was observed to be congested to the last degree. The ventricles contained no effusion whatever, and there was no trace of ruptured blood vessels in its substance, which however was greatly congested.

Chest and Abdomen.—Old adhesions were detected between the pleura pulmonalis and pleura costalis of the right side of the chest, the lung of the same side containing more blood than natural. The heart, left lung, and abdominal viscera, were all healthy. The alimentary canal contained a small quantity of feculent matter.

Remarks.—The foregoing cases present a remarkable contrast, the first being a case of hysteria simulating apoplexy, the second presenting an example of apoplexy from cerebral congestion, which, most probably, was connected with the morbid changes in the lungs, affording an impediment to free circulation of the blood through them. She had been affected with headache at different periods for a long time. The case of hysteria affords an example of the necessity of not having recourse to blood letting in every case of "fits," although the popular opinion may be in favour of it. The mother of the girl in this case was dissatisfied at first that I did not bleed her daughter, but when she found that the patient was able to walk to the Dispensary on my next visit, as I said she would be able to do, her anxiety in regard to bleeding ceased.

DEAFNESS SUCCESSFULLY TREATED AND CURED BY MEDICATED VAPOUR DOUCHE AND THE MEATUS EXTERNUS DILATED BY TENTS, &c.

To the 'Editor of the Medical Times.'

Sir,—Should you deem the enclosed interesting case of deafness deserving a place in your invaluable journal I shall feel obliged by your insertion.

I am, Sir, your obedient servant,
William Thornton,
Army Surgeon,
M. R. C. S. L.

, Baker Street, Portman Square, 25th Oct., 1842.

A gentleman residing in London of general good health, but of a nervous temperament has been *deaf twenty-three years*, in consequence of frequent *colds*, but his hearing was so defective as to render his life almost a burden to him; he had applied to several (so styled) *Aurists*, &c., who had prescribed stimulating oils, lotions, and blisters without benefit. Upon examination of the *meatus auditorius externus* of the right ear, I found it was much contracted in its calibre, by the thickening of the surrounding parts and especially the great increased density of the cuticle which had a *white, rosy* appearance, extending to the bottom of the auditory canal (near the insertion of the membrana tympani). On injecting warm water, a dull obtuse sound was produced, as if some dense medium was interposed (the patient said that he felt something rattle in his ear); the orifice was nearly closed and it was with some difficulty that a probe entered it; a sensation to my touch was conveyed different from that which would have been produced by the contact of a healthy membrane; whilst at the same time it did not cause the usual painful sensation. The sense of hearing was nearly *lost* but a watch applied to the ear was audible. He could with difficulty force air into the tympanum by powerful expiration; the nose and mouth being closed, air passed freely through the left *eustachian tube* into the outer ear, the *membrana tympani* being *perforated* (the patient was not conscious of this circumstance). On passing the catheter into the *eustachian tube* it was clearly shewn to be narrowed; the *air douche* passed with some gurgling noise into the tympanum, and in the left tube the air passed freely; hearing distance of this ear was six inches.

On syringing the meatus and dilating the orifice there was not the slightest appearance of *cerum* but the same *rosy white* thickened cuticle appeared to extend as far as the eye could reach. These circumstances led me to think that it was possible the *deafness* depended on a thickened state of the cuticle reflected over the *membrana tympani*, similar to that which lined the meatus, or some morbid secretion existing between this cuticular layer and the membrane. To remove this cuticular lining I used a strong solution of *acetate of zinc*. In a few days, upon syringing with tepid water, several dark pieces of cuticle were washed out and the orifice dilated so much as to give a clear view of the state of the *membrana tympani* which appeared *dull and dry*. The unpleasant noise the patient had formerly complained of was now removed and from this time his hearing daily improved to the great delight of the sufferer. The *medicated vapour douche* used daily, after several sittings the *vapour* passed freely into the tympanical cavities, and his hearing gradually increased. The contraction was dilated by tents and the auditory passage anointed with ungt. *hydrarg, nitrat. dilut*, and ungt. iodid. comp. rubbed behind the ear and on the mastoid cells; at the same time *dec sarsæ concent.* with *potassæ iodidum.* administered for six weeks; under this treatment his hearing functions were restored and cured.

P.S.—This gentleman had been under the treatment of an *Aurist* five months without receiving any benefit and said that his deafness was much increased.

HYDRIODAS POTASSÆ.

To the Editor of the 'Medical Times.'

Sir,—The few following details, as exemplifying, in a striking degree, the occasional violent effects of a much used and favorite preparation of iodine, hydriodas potassæ, you may perhaps think not unworthy of a place in your widely circulated Journal.

As I had been some time previous to March last, labouring under a slight, partially diffused, chronic eruption, which I attributed to derangement of the chylo-poetic viscera, as a primary exciting cause, I resolved on trying the effects of hydriodas potassæ for its removal; with that view, I prepared a simple solution, intending to take the remedy in divided doses of 5 grains twice a-day. In making up the first dose, either from inadvertency, or from some interruption at the moment, I swallowed a portion, which was afterwards calculated to have contained 9 grains; the taste of the draught at

the time, felt pungent and characteristic. The dose was taken about 4 P.M., and, with the exception of the pungent sensation in the fauces, no other particular feeling was occasioned; except, perhaps, a degree of languor, until on going to bed at 10 P.M., I had the sensation of a common inflammation in the fauces, along with the continued characteristic impression at first given by the medicine. I passed a restless and sleepless night, from the presence of considerable febrile excitement, an almost constant discharge of saliva, and a most troublesome irritation in both eyes, inflammation of their conjunctival surface being produced, which, also, occasioned much pain and constriction in attempting to shut the eyelids; my gums were tender, and some pain was experienced by pressing on the regions of the parotid and sub-maxillary glands. The increased secretion of saliva and feverishness, subsided in the morning; and the inflammation of the eyes, gums, and throat, did so likewise towards evening: and next day, there was scarcely a trace of the peculiar effects of the medicine left behind.

In order to put it beyond question, that these rapid and somewhat violent effects, were occasioned by the drug, although, at the same time, aware that alarming symptoms had before been often observed and recorded, I collected the salivary discharge from the handkerchief I had used, after moistening it still further with water, and submitted it to the starch test, when there was immediately thrown down a copious deep blue precipitate.

My attention was the more especially directed to the uncertain effects of this valuable medicine, as I had not long previous to the time I tried it in my own person, used it to the extent of 6½ drachms, in divided doses of 10 grains three times a-day, in the case of a delicate lady, suffering from an obstinate, and long continued affection of the gums, apparently depending upon disease of their deeper structure; and, although, in this instance, its administration was not followed by any marked beneficial result, still there was no bad symptom ever complained of. I believe, however, that I would not have prescribed the remedy so largely, had I not previously observed it recommended in the same doses, and for a like affection. I may add, that the medicine, applied in both cases, was procured from one of our most respectable drug establishments, the Glasgow Apothecaries' Company.

The rapidly marked, and evanescent effects of this medicine, in my case, although, easily explained by peculiar susceptibility of habit, appear to me, to be not devoid of interest; and, should you consider it so, I shall feel obliged, by the insertion of it, in your valuable Periodical.

I remain, sir,
Your most obedient servant,
GEORGE LAING.

Ferry-port on Craig, 22d Oct. 1842.

DEATH FROM TARTAR EMETIC.

JUSTICIARY COURT OF SCOTLAND.—DISCRETIONARY POWERS OF THE PUBLIC PROSECUTOR.

(For the 'Medical Times.')

As illustrative of the views entertained in Scotland, of the responsibility of druggists, who, it may be remarked, are often grocers, or dealers in small wares, as well as drugs, the following may be quoted, as given in the *Perthshire Advertiser*, of Oct. 20th of the current year:—"Perth, Thursday, Oct. 13th.—The Court assembled this morning at ten o'clock (when, from the illness or unavoidable absence of one of the ordinary judges, the Lord Justice General, who is also President of the Court of Session, and the Lord Justice Clerk presided). Robert Henderson, grocer, Leven, County of Fife, and William Lawson, shopman to the former, accused of culpable homicide; he, Robert Henderson, having not such knowledge of medicines as to qualify him for a druggist, and having recklessly employed the said William Lawson, although he too was ignorant of the proper kinds and quantities of medicines that could be safely given; and that the said William Lawson, on 20th January, 1842, sold to Ann Johnstone *sixty grains of tartar emetic* for her father, James Johnstone, who, on taking that quantity, suddenly became very ill, and died in consequence. Both panels pleaded "Not Guilty." The Advocate Depute then stated to the court that it was his desire that the diet should be deserted against the prisoners. The case was before the last Assize held here, and had since been before the High Court of Justiciary at Edinburgh; besides their regret for the unfortunate circumstance had been lasting and severe. Under these circumstances, he thought that he was justified in that request, the more especially as it was not altogether clear that the person died solely in consequence of the medicine administered to him. The diet was accordingly deserted against both prisoners."

In the absence of information as to the particulars of this case we are precluded from making any remark as to the previous state of Johnstone, and have no doubt that the public officer (acting for the Lord Advocate) conceived that *he* was only doing his duty, in following the very lenient course adopted, in dismissing the prisoners from the bar of court. But it may very properly be asked, what security have the public against a repetition of a similar course of reckless procedure on the part of these village "Hornbooks," (see Burn's "Death and Dr. Hornbook"), whose ignorance is only equalled by their presumption and cupidity. The conclusion drawn by the public prosecutor, "that it was not altogether clear that the person died *solely* in consequence of the medicine administered to him," is evidently at variance with the previous part of the libel, when it is stated that, James Johnstone, who on taking that quantity, *suddenly* became very ill, and died in consequence."

The opinions of *Rasori*, as to the effects of antimony are well known, and at variance with the general experience of medical men. But in the admitted powerful effects of tartar emetic, even in small doses, it requires a more than ordinary stretch of judgment, to suppose that *sixty grains of tartar emetic*, could in ordinary circumstances, be administered without danger to life. And that ignorant and unqualified persons, should be permitted even, to sell such medicines is a libel on the laws of the land.

ROBERT ANNAN, L. R. C. S. E.

Kinross, Oct. 21, 1842.

A CASE OF TETANUS TREATED SUCCESSFULLY, BY OPIUM IN LARGE DOSES.

(To the Editor of the 'Medical Times.')

SIR,—Should the accompanying case be deemed worthy of a place in your valuable Journal, you will much oblige,

Your obedient servant,
THOMAS JOHNSTON,
M.R.C.S., &c.

Westerham, 26th Oct. 1842.

Sept. 18th. John Smith, a wheelwright, aged 20, nearly cut off the extremity of the middle finger of the left hand, with an axe. The wound extended about half way across the nail, near its root; the bone was completely divided, and the artery bled so profusely, that I was obliged to secure it by ligature. The wound was closed by strips of adhesive plaister, and for some days, union by the first intention appeared probable. The ligature came away with the dressings on the eighth or ninth day. About this day he was dressed daily with unguentum resinæ, the wound beginning to slough and look unhealthy; however, he suffered little or no pain. On the 24th, my assistant, after dressing him, informed me that he complained of stiffness in his jaw, and a little soreness of throat, for which he had given him a calomel bolus, and an aperient draught, supposing the symptoms were caused by cold; but, the patient himself imagined, they were occasioned by his having eaten a large quantity of nuts. Judging, from this account, that he was affected with tetanus, I called on him the following morning, and found his jaw so nearly closed, that I could not introduce the point of my fore-finger further than about half way up to its nail. The muscles of the neck, particularly the mastoidei, felt rigid; he complained of great stiffness about the neck and jaw, but had no difficulty of swallowing: the wound caused little or no pain. I immediately gave him sixty drops of tincture of opium, and ordered the same dose to be repeated at bed-time, and the finger to be wrapped in a bread-and-water poultice. The opening medicine given him yesterday operated several times.

26th.—No material alteration: says he slept well, but that his neck and shoulders are very stiff. Desired him to remain in bed, in order that perspiration may be promoted, and take the following medicines:

℞ Pulveris Opii, gr. vj.
Camphoræ ℈j.
Hydrarg. Chlorid. gr. iij.
Confect. Opii. q. s.
M. div. in pil. xij cap. j. 2da. hora.
℞ Spiritûs Ætheris Comp. ʒj.
Tincturæ Lavand. Comp ʒss.
Misturæ Camphoræ, ℥xi. m.
Fiat mistura cap. cochl. ij post pil.

27th.—Something better to-day: I can now introduce the point of my finger into his mouth, nearly up to the first joint; stiffness extending between his shoulders, but he can readily bring his chin down to the sternum, and move his head in all directions. No difficulty of swallowing, or spasmodic paroxysms, but a constant aching pain: pulse natural; tongue furred; thirst moderate. Repeat the medicines. Ordered to take wine and nourishing broths; but, to remain in bed.

28th.—Much the same: no stool since the 25th.

℞ Infusi. Sennæ, ℥ij.
Statim sumendus.
Repetantur Pilulæ et mistura.

29th.—Bowels constipated: in other respects as yesterday.

Repetatur Infus. Sennæ.
℞ Aloes.
Camphoræ, aa. ʒss. m.

Divide in pil. xij. cap. ij. 2da. horâ donec alvus respondet bene.

Oct. 2nd.—Bowels have been very freely relieved. He can now open his mouth sufficiently to admit my finger with tolerable facility; but, the muscles of the neck and back, are so powerfully contracted, that he can neither move his head, which is strongly drawn backwards, nor bend his body; complains of great pain in his shoulders and hips. A large blister to be applied between the shoulders and another to the lumbar region.

℞ Pulveris Opii.
Camphoræ.
Pulveris Ipecac. aa. gr. xxiv.
Ext. Hyosciam, q. s. M.
Fiant pil. xij. cap. i. 2da. horâ.
℞ Spir. Æther. Co.
Spirit Ammon. Co.
Tinct. Lavand. Co. aa. ℥ss.
Mist: Camphoræ, ℥xss. M.
Fiat mist. sumat cochl. iij. amp. post pil.

3rd. Somewhat better to-day: removed the slough and carious bone; wound granulating, and gives very little pain; says he sleeps well; has no headache; thirst and tendency to fever; moves his arms and legs with ease; but, cannot bend his body, or raise his thighs. No stool since the 1st.

℞ Pil. Hydr. Chlorid, gr. iij.
horâ somni.
℞ Infusi Sennæ, ℥ij.
mane.

The other medicines to be omitted till the bowels have been evacuated.

5th—No material alteration: the bowels still costive; a common glyster to be injected, and repeated in the evening, if necessary.

7th.—Much the same: lies like a log in the bed, having no power to move his head or trunk of the body. Two enemata were thrown up, but with great difficulty, in consequence of the strong muscular action, and caused so much pain, that he begs they may not be repeated.

℞ Ol. Ricini, ℥j.
Statim sumend. et rep. post tres horas si opus sit.
℞ Ext. Hyosciami.
Tinct. Opii, aa. ʒj.
Spiritus Æther. Comp. ℥ss.
Aquæ Menth. Pip. ℥vi. M.
Cap cyathum post operationem Ol. Ricini.

8th.—Both doses of castor oil were taken, and produced several evacuations. Rigidity still continues unabated.

Repetatur mistura et Adde Tinct. Opii, ʒss.

9th.—No abatement of rigidity, except that he opens his mouth with rather more freedom. Dislikes the mixture; several doses of which, have been immediately rejected; very little sleep.

℞ Opii, gr. iv.
statim.
℞ Tinct. Opii, ʒiij.
Tinct. Lavandulæ. Co. ʒij.
Aquæ Pulegii, ʒviij. M.
Cap. ut antea.

10th.—No sickness since yesterday: rigidity much the same; but less pain.

℞ Pulveris Opii.
Camphoræ, aa ℈j. M.
Divide in pil. viij. Cap. ij. a sing. dose misturæ.

11th.—Much better in every respect: sleeps well; but not more than patients usually do after a full dose of opium.

Repetantur Pil et Mistura.
The castor oil to be repeated, if necessary.

13th.—Has omitted several doses of his mixture and pills, having slept well. Castor oil repeated yesterday, operated effectually. Can raise himself a little, but not sufficiently to sit up.

Repetatantur Pil. et Mistura.

20th.—Much better: managed to sit up, with some difficulty. His mixture and pills were continued until the 23rd, when I found him so far recovered as to be able to walk across the room. The last two days he has slept almost continually. Has been sick several times this morning, and perspires profusely: very little pain, or rigidity; opens his mouth nearly to its full extent. Conceiving now the further use of opium to be unnecessary, I discontinued it altogether, and ordered the following mixture, and a continuation of his wine and nourishing diet.

℞ Spiritus Ammon. Co. ʒij.
Mist. Camphoræ, ℥iij.
Infus. Gentian. Co. ℥v. M.
Cap. cyathum ter die.

He continued this plan till the 25th; when, being perfectly recovered, I desired him to discontinue all medicines; dressed his finger with unguentum resinæ (which had hitherto been poulticed), and recommended him to use daily exercise in the open air.

I deem it necessary to state, that he can, at the time of my writing, open his mouth as well as before the receipt of the injury, and eats with the same freedom and ease, as hitherto.

Thomas Johnston.

THE SYDENHAM PUBLISHING SOCIETY.

To the Editor of the 'Medical Times.'

Sir,—Allow me through the medium of your Journal to draw the attention of the members of the medical profession, to a proposal that has been occupying the attention of several gentlemen for some time past for the formation of a medical society, on the principle of the Camden Society, for the re-publication of valuable and scarce medical works of this and other countries, one copy of each book to be distributed to every paying member. My object in addressing you is to beget discussion and advice, as to the best mode of establishing the society, and to ascertain, as far as practicable, the amount of interest that, would be taken in it by the profession, and consequently the degree of support to be anticipated.

I find, by a document now before me, that the Camden Society, which was instituted in 1838, numbered 900 members ere the close of the first year of its existence. The members were at first limited to one thousand, but the applications were so numerous, that a large number were speedily admitted. It was formed for the publication of early historical and literary remains in the most convenient form, and at the least possible expense that is consistent with the production of useful volumes. The governing body consisted of a president, council, auditors, and secretaries in the municipal cities of the kingdom. It is now, I believe, one of the most prosperous societies in England. The success attending the Art-Union and other institutions, shews the advantages to be derived from the aggregation of small subscriptions, and I see no reason why the medical profession should not be enabled to originate and sustain a society, the professed object of which is to acquaint them with the buried lore of the princes of medicine, buried, I say, in works, which are inaccessible to the great majority of practitioners.

The plan pursued by the Camden Society might, to a certain extent be adopted by the Sydenham. The number of members should be unlimited, all classes of the profession admitted as subscribers, and one guinea annually be the amount of the subscription. A governing council should be appointed to make the necessary arrangements, control the expenditure, and select the works destined for republication. These I would not confine solely to the works of our predecessors; there are many productions constantly issuing from the press of our continental brethren, with which we ought to be acquainted, but from their non-publication in this country, are unable so to be. An occasional translation, or original work, might, therefore, be added to the Sydenham collection without injury to the members. The medical profession numbers, as I think, upwards of 20,000 in the three kingdoms, and it is not surely too much to expect that one-tenth of these would be anxious to avail themselves of the advantages offered by the establishment of such a society. With that number, from the calculations I have made, I am assured it is perfectly possible to supply ten volumes annually to each member, or books to the value of five guineas for the annual subscription of one, nor would others limit its success, for it must be borne in mind that every additional 100 members would be equivalent to another volume annually. The prospects thus offered are not the result of a too ready credence, but are drawn from calculations carefully and repeatedly made—nor will they surprize any one, when it is remembered that the profits of the bookselling trade are not to be accounted for, the only incidental expenses beyond the mere publication, being for chambers, clerk, coals, &c. Original works, when given, will of course make a difference, as the author must be paid for his composition. I should be glad to learn the opinions of your subscribers with respect to this proposal.

I am, Sir,
Yours obediently,
F.

REVIEWS.

Observations on the Admission of Medical Pupils to the Wards of Bethlem Hospital for the purpose of Studying Mental Diseases, Second Edition, by John Webster, M.D. one of the Governors, &c. &c.

The medical profession and the public are indebted to Dr. Webster for this pamphlet. It is indeed strange that a disease that degrades man below the very brutes, should be so very little studied by the profession, or that so little opportunity should be afforded the profession of acquiring a practical knowledge of this most lamentable of all ailments. Yet such is the fact and we can hardly account for it upon any other principle than the incorrect notions so long prevalent in society and in the profession regarding the nature of insanity. So long as insanity was believed to be a disease of the mind, its nature was considered mysterious and inscrutable and no inducement held out for its investigation or study. But since insanity has been discovered and prov d to arise from morbid conditions of the brain—to depend upon corporeal causes—to be in fact a corporeal disease, susceptible of cure like every other corporeal malady, more correct and rational views of its treatment have been adopted and the profession are now alive to the horrors of the old practice. Lunatic asylums should be viewed as so many hospitals for the treatment of diseases of the brain and no argument can be used for excluding medical students from witnessing the practice of such hospitals that is not equally cogent in reference to every other infirmary or medical hospital that exists. These are views now generally entertained by the profession but the public are not so well informed, and the pamphlet of Dr. Webster written for the enlightenment of the Governors of Bethlem Hospital cannot fail in producing a good effect. Dr. Webster has both our thanks and good wishes for his laudable efforts.

Commentaries on Some Doctrines of a Dangerous Tendency in Medicine, and on the General Principles of Safe Practice. By Sir Alexander Crichton, M.D., F.R.S. Physician to the Emperor of Russia, &c.

SECOND NOTICE.

In accordance with our promise made the week before last, we resume the consideration of this very interesting work.

The "Second Commentary" commences with an account of the typ ous fever in London in 1790. At this period the doctor was one of the physicians to a public Dispensary in Featherstone Buildings, Holborn, and he informs us that he does not recollect one year to have passed over while he was attached to that institution—

"In which typhous fever did not originate almost every spring and autumn; and also frequently during winter, at one and the same time in several distant spots; but always in dirty and narrow lanes, and in damp courts, in which the wretchedly poor inhabitants were crowded together in low confined apartments,"—p. 42

The doctor observed that this fever was most prevalent in the lanes and courts of St. Giles, chiefly tenanted by the low Irish, and the disorderly of both sexes, and on his appointment some years after to the Westminster Hospital, he witnessed the same train of symptoms among the poorer classes of Pimlico, and its neighbourhood, for at that period, he tells us, the parish bore a very different appearance from what it exhibits at present. It was then not so well drained, and as many parts are below the level of the river at high water, it partook at times of the unhealthy malaria of marshy land; so that typhous fever, and bad intermittents, frequently prevailed among the poor. He then adds:—

"The recollection of these facts often brings to my memory many thoughts which presented themselves to my mind in those days, relative to the necessity of a well-regulated and duly authorized medical police, or board of health, not only for London, but for all our great cities, and more especially for some of the densely-peopled manufacturing ones, in which there was a disgraceful neglect of the health of the inhabitants, as far as the free ventilation of air and removal of filth, and other local causes of malaria were concerned,"—p. 42-3.

The Medical Times can do little more than re-echo this opinion. Had a medical police existed, the atrocious crime of erecting a hospital in the midst of a reeking grave-yard, crammed to the surface with the putrid bodies of the dead, as is the case with the charnel-house (so called) in Portugal Street, would not, *could not*, have been perpetrated. *The Medical Times*, however, has so recently exposed this monstrous violation of decency, this unblushing outrage on common sense, this desperate attempt on public health, that it would be tautological to go the same ground over again; but it is impossible to refrain from adding, that a more wicked, a more selfish, or a more disgraceful act of heartless cruelty to the poor, of irreverence for the dead, and contempt for the feelings of the living, was never perpetrated by Nero in the zenith of his depravity, or Ivan, the Terrible of Russia, in the fulness of his flagitious career, though the latter sometimes indiscriminately assailed peaceful villages with his armed myrmidons, and setting fire to the houses, butchered man, woman, and child, with a vivid and remorseless cruelty, that seemed rather the attribute of a fiend than the vice of a human being. Indeed we do not know but that Ivan's conduct was less cruel in its consequences, for his "*single* blow left little work for two," but the Portugal Street abomination forms the nidus of disease, which in its ramifications leads—God knows where!

To return:—Typhus, when first appearing in the localities of St. Giles and Pimlico, did not appear to be contagious, but when several members of the same family were attacked, and were confined in the same apartment, shutting themselves up close "to keep out the cold," a poison was generated by the confined exhalations of their bodies, "which soon affected many of the neighbouring families; but still the fever seldom spread far."—(p. 43) It generally assumed the character of mild typhus, but when a very cold and damp autumn succeeded a very *hot* summer, it had a severer character, and was frequently developed with all the aggravated symptoms of typhus gravior, complicated with petechiæ and vibices.

Our author does not recollect to have seen the bilious synochus of Sydenham prevail as a general epidemic, though a few solitary cases appeared now and then. In general it was easily cured, if in the beginning the brain was not implicated, and profound coma and stupor were absent. Neither did violent delirium, though an untoward symptom render the disease incurable. A free admission of cool, or even cold air, leeches to the neck, and blisters on the inside of the thighs, and between the shoulders; frequently washing the head, face, and neck, with cold vinegar and water, together with the internal administration of the nitrate of potass, and the liquor ammoniæ acetatus, to which were added the tartrate of antimony and calomel in *very small* doses frequently repeated, were the most effectual remedies for diminishing the cerebral affection. Delirium in a moderate degree was never considered as an unfavourable symptom. In no case was the *Lancet* employed for its removal. It was never deemed necessary. The violent headache and mild delirium generally yielded to a blister between the shoulders, when assisted by the other remedies just enumerated. But when the disease began with a profound coma, its termination was almost always fatal, p. 44.

At this period Sir Alexander says the treatment of typhus was nearly uniform—it was the same which had been handed down from the times of Sydenham; and the physicians, whose assistance and advice the doctor was accustomed to solicit, were the father of the late Dr. Warren, Dr. David Pitcairn, and Dr. Reynold's. All these practitioners abstained from blood-letting at every period of the disease except under very particular circumstances. Emetics and purgatives were sparingly employed, the practice agreeing in this respect with the advice of Cullen. The bowels were relieved when requisite by enemata, and in the first stage of the fever, all tonics and stimulants were avoided, while refrigerants and the saline diaphoretics, with small doses of antimonial wine, tartar emetic, or ipecacuana were freely and frequently given. Some practitioners gave the compound powder of contrayerva as a diaphoretic in the first stage. In the second and subsequent stages of the disease, when sustaining the failing powers of the patient was imperatively indicated, mild nutritive drinks, wine in suitable doses, decoction of the Virginia snake root, infusion, or decoction of cinchona, to which the saturated lemon juice, or Riverius's draught was almost always added when the skin was dry. (p. 45).

To allay hickup, tremor, irritation, and nervous languor, musk, valerian, camphor, Hoffman's ether and laudanum were exhibited, very often the mithridate or theriaca, or in lieu of it, the old confectio cardiaca with, or without opium, was administered also.

Varieties of this fever of course demanded variety of practice. For example,—bilious typhus required the free use of emetics, and afterwards calomel, or other active purges; while the petechial typhus called for a liberal use of the mineral acids, and for larger doses of wine, which was found to be the best of all febrifuges.

Blood, even when the fever commenced with catarrhal symptoms and pleuritic pain, was seldom extracted, and even when venesection was resorted to, the quantity lost did not exceed ten ounces.

"It was seldom repeated a second time; and yet I have not seen typhus fever in all its forms more successfully treated than it was at that time. I have lived long enough to have witnessed many strange innovations in the mode of treatment, and I am sorry to add, that, judging by the results, they cannot be counted as improvements,—p. 46.

(To be Continued.)

MEETINGS FOR THE ENSUING WEEK.

Nov.	7, Monday,	Medical Society of London, 8 P.M.
		Entomological Society, 8 P.M.
	8, Tuesday,	Royal Med. Chir. Soc., half past 8 P.M.
		Zoological Society, half past 8 P.M.
	9, Wednesday,	Royal Medico Botanical Society, 8 P.M.
		Westminster Hospital Medical Society, 8 P.M.

*** The French works above announced, may be had through Dulau and Co., Soho Square.

MEDICAL NEWS.

QUACK MEDICINES.—In the *Nottingham Journal* of last week, appeared two notices of inquests:—one on a child, who died in consequence of a dose of *Godfrey's Cordial* being administered to it by its mother, but without any evil intent; another on an infant, who, according to the medical evidence, died from convulsions, probably caused by the improper and incautious administration of a certain compound, called *Dale's Mixture*. Mothers ought to know and remember, that most of these advertised mixtures for children contain *laudanum*—a medicine which ought never to be administered to children, except by the express direction of a properly qualified medical practitioner. *Gateshead Observer*.

INSURANCE COMPANIES AND MEDICAL MEN.—At a meeting held at the Lion Hotel, Shrewsbury, on Tuesday Oct. 26th, Dr. H. Johnson in the chair, it was unanimously resolved by the undersigned, on the motion of R. Cartwright, Esq., seconded by W. I. Clement, Esq. That in unison with the resolutions of a British Medical Association, passed in 1837, the present meeting pledge themselves not to answer the enquiries of Insurance Companies, unless accompanied by a fee of one guinea.—Robert Cartwright, Thomas Jones Drury, M.D. James Bratton, William Onions, Sam. Wood, Edwin Foulkes, John Dickin, I. Y. Arrowsmith (for Wynne, Arrowsmith, and Stephens) W. J. Clement, Daniel Crawford, Henry Keate, W. Griffith, George P. Gill, C. T. Hughes Clarke, I. N. Heathcote, Secretary, Henry Johnson, Chairman. Mr. Piddock, Surgeon in the same district, has written to us, expressing his full agreement with the object of the institution.

GRATITUDE FOR MEDICAL SERVICES.—The inhabitants of Ballyshannon are about to erect a Monument to the memory of Dr. Crawford, late Superintendent to the Dispensary in that town. Subscriptions for this purpose have already been handed in to the amount of nearly £200. Dr. Simon Shiel has been elected his Successor.

ROYAL COLLEGE OF SURGEONS, LONDON.

List of gentlemen admitted members on Friday October 28th, 1842 :—

W. M. Dalgliesh, M. M. Ball, J. Rogers, J. H. Forster, H. C Hildash, E. Moore, J. Wade, R. B. Penny, W. Dalton, J. H. Steele, R Barnes, T. S. Lee.

ADVERTISEMENTS.

REGULATIONS OF THE ROYAL COLLEGE OF SURGEONS,

MEDICAL PRACTITIONERS.

BY a late REGULATION of the College of Surgeons, Gentlemen in actual Practice, desirous of obtaining the College Diploma, are to be admitted to Examination without producing any Certificates, either of Lecture or Hospital Practice, until January next inclusive, have merely to stand the issue of a Fair Practical Examination. Mr. Dermott qualifies for Examination at the College, and to meet the convenience of Practitioners and Senior Pupils, receives Gentlemen into his House by the month. Pupils, who have completed their curriculum of Study, previously to the present month, according to the old regulations, are permitted to present themselves for Examination, according to the said regulations until January next. Apply to Mr. Dermott, Charlotte Street School of Medicine, 15, Charlotte Street, Bloomsbury.

TO MEDICAL STUDENTS.—Dr. POWER will continue during the season to hold his CLASSES for the Instruction of Gentlemen preparing for Examination at Apothecaries' Hall, the College of Surgeons, London University, and Medical Boards.

Class hours, 8¼ till 12; 2½ till 1; and 5¾ till 7.

Inquire at Dr. P.'s Lecture-room, 7 Maze-pond, Guy's Hospital, or at 37, Nelson-square, Blackfriars.

MEDICAL OFFICER.

John Clendinning, M.D., F.R.S., 16, Wimpole Street, Cavendish Sq.

STANDING COUNSEL.

The Hon. John Ashley, New Square, Lincoln's Inn.
Mr. Sergeant Murphy, M.P., Temple.

SOLICITOR.

William Bevan, Esq., Old Jewry.

BANKERS.

Messrs. Drewett and Fowler, Princes Street, Bank.

This Institution is empowered by a Special Act of Parliament, and is so constituted as to afford the benefits of Life Assurance in their fullest extent to Policy-Holders, and to present greater facilities and accommodation than are usually offered by other Companies. The decided superiority of its plan, and its claim to public preference and support, have been proved incontestably, by its extraordinary and unprecedented success.

*** Assurances may either be effected by parties on their own Lives, or by parties interested therein on the Lives of others.

The effect of an Assurance on a person's own life is to create at once a Property in Reversion, which can by no other means be realised. Take, for instance, the case of a person at the age of Thirty, who by the payment of £5. 3s. 1d. to the Britannia Life Assurance Company, can become at once possessed of a bequeathable property, amounting to £1000, subject only to the condition of his continuing the same payment quarterly during the remainder of his life,—a condition which may be fulfilled by the mere saving of eight shillings weekly in his expenditure. Thus, by the exertion of a very slight degree of economy—such, indeed, as can scarcely be felt as an inconvenience, he may at once realize a capital of £1000, which he can bequeath or dispose of in any way he may think proper.

A Board of Directors in attendance daily at 2 o'clock.

Detailed Prospectuses, and every requisite information as to the mode of effecting Assurances, may be obtained at the Office.

PETER MORRISON, Resident Director.

ORIGINAL MEDICAL GLASS AND FIXTURE WAREHOUSE.

ANSELL AND HAWKE, of No. 8, Great Queen Street, Lincoln's Inn Fields, begs to inform Gentlemen commencing or altering in the above Profession, that they have a large assortment of Drawers, Bottles, Jars, and every requisite for completing Shops or Surgeries, on the most moderate terms. Most satisfactory references can be given as to style and quality. Plans and Estimates furnished, free of expense.

Valuation of Stock and Fixtures.

CURVATURES OF THE SPINE, DEFORMITIES OF THE LIMBS, &c.—Mr. AMESBURY'S PRIVATE ORTHOPEDIC ESTABLISHMENT for the PREVENTION, RELIEF, and CURE of CURVATURES of the SPINE. The time required for restoration of the Spine, in curable cases, varies from three to twelve months. In very bad neglected cases a longer period is necessary. The health and strength are greatly improved by the treatment adopted. In cases of In-knee and Out-knee, In-ankle and Out-ankle, the limbs are commonly restored to their natural line in a few days; a longer period, however, is necessary to complete the cure. Particulars may be obtained by application to Mr. AMESBURY, at his Residence, 12, Devonshire Street, Portland Place, London. For Illustrations see his

PRACTICAL REMARKS ON DEFORMITIES of the SPINE, CHEST, and LIMBS, STIFFNESS and WEAKNESS of the JOINTS, MUSCULAR CONTRACTIONS and MUSCULAR WEAKNESSES, Partial and General. 4to. £1. 11s. 6d. Published by LONGMAN & Co., Paternoster Row, London. By the same Author, PRACTICAL REMARKS ON FRACTURES of the TRUNK and EXTREMITIES, with Plates and Cases, 2 Vols. 8vo. £1 5s.

FRENCH LANGUAGE.

M. DE BEAUVOISIN'S ORIGINAL SYSTEM.

MONS. MARIOT DE BEAUVOISIN (from Paris) begs to inform his Pupils and the public that he is now resuming his CLASSES at his Chambers, 33, Lombard Street, City, and 108, Strand, for the Season. The terms, the days, and hours of attendance, are the same as before. A Prospectus may be had at either of M. B. residences.

N.B.—M. De B.'s Original System is published by SOUTER & LAW, 131, Fleet Street, and sold by all booksellers and venders of new Publications. Price, each Lesson 9d.

Every learner should unhesitatingly adopt this system.—COURT GAZETTE.

This work is the most useful that has yet appeared,—creditable at once to the skill of the writer, and remarkable for knowledge, acuteness, and judgment. NEW WEEKLY MESSENGER.

We can recommend it to our readers as being one of the best for acquiring a knowledge of the French tongue. AGE.

It appears to us to be entirely unique. NEW MONTHLY BELLE ASSEMBLEE.

It is the best introduction to the French language we have seen, and the system is calculated to make a sound scholar. MONT. ADV.

We consider this little work as a decided acquisition PATRIOT.

It is on the Hamiltonian system, but with great improvements, &c. The plan appears to us very satisfactory.—DISPATCH.

It partakes of the Hamiltonian system but in our opinion is infinitely more effective.—BELL'S LIFE.

MR. FOSTER'S SALE.—The great SALE of LINENDRAPERY GOODS announced to take place by Mr FOSTER, is NOW ON at the corner of Fleet Street, being the entire Stock of the largest wholesale trading firms in the City.

Mr FOSTER is instructed to sell the whole of these goods by hand to retail customers, having represented to the Proprietor the difficulty of effecting an efficient sale at his Auction Rooms, where the nobility and persons calculated to purchase expensive linens and curiously fine damask cloths, &c., would not attend.

As these goods have been accumulating some years, many of the articles are of a superior fabric to those of the present day (since steam has so completely superseded hand-loom weaving). Ladies or families who would not object to antique patterns, or uncommon styles of Silks, Shawls, Prints, Muslins, &c., will find some of the richest manufactured goods at prices unprecedented.

The magnitude of this Stock can only be known by inspecting the Sale-rooms, which, from the immense quantities shown on this occasion, offer peculiar advantages to Shippers, Wholesale Dealers, Emigrants, or families furnishing.

The lower warehouses contain hundreds of pieces of Brussels and other Carpets, Blankets, Flannels, with various descriptions of Woollen goods.

In the upper rooms are cases of superb Damask, English and Foreign Table Cloths, and various bales of Irish, Scotch, and Russia Linens.

The sale for this week consists principally of Linens of the finest character, and the reduction is guaranteed to the following extent, as will be seen on inspection.

	s.	d.
380 pieces of Bennet's finest Coleraine Linens, of the original value of 1s. 9d. and 2s. per yd., will be sold at 25 yds. for	25	0
160 pieces of the finest numbers, suitable for the wear of the nobility, or persons wishing fine Linens, 25 yds. for	42	0
About 1,100 pieces of Knox's stout Linens, that were bought from him direct at sixteen pence half penny per yard averaged, will be reduced to 26 yards for	21	0
1,000 pieces finest Huckabacks for chamber towels, six-pence three farthings per yard.		

The Sheetings and Table Linens are all of the finest descriptions, the coarse qualities having been sold to the trade. The prices will be, for Linen Sheetings, fine qualities, 3 yds. wide, 10s 6d the pair, and those of the very finest descriptions, full bleached, and of the original value of 5s. 6d. or 6s. per yd., will be reduced to 20s. the pair.

The following is a list of Table Linens, as per book, rendered to Mr. Foster —

	s.	d.
1,300 Table Cloths, all 2 yds. square, finest damask, each 3s. 6d., or by the dozen	40	0
500 dozen of Breakfast Cloths, yard and a half square, all each 1s. 2d., or the dozen	13	6
600 superb Damask Cloths, full 3 yds. long, valued as per book, at 25s. each, will be sold each	10	6
About 160 strong Linen ditto, full 3 yds. long, suitable for Kitchen use, each	3	6

Besides about £3,000 worth of the most curious and expensive Table Cloths and Napkins, many with coronets, landscapes, and emblematic designs, varying from three to eight yds. long, many of the original value of ten guineas each, will be sold, being six yards long for 35s. and 40s. 1,600 dozens of Napkins are reduced from 50s. to 8s. 6d. the dozen, and several sizes as low as 3s. 6d. to 5s. 6d.

Mr. Foster directs particular attention to the stock of Carpets, being in value about £11,000, and contains Brussels Carpets of the most superb patterns. On the most expensive qualities the reduction will be the greatest, and ladies who do not desire the newest patterns will find some superior qualities there offered at 2s. to 2s. 6d. per yard, and the most splendid qualities at 2s. 9d. to 3s. Also a lot of real Kidderminster Carpets, from 1s. 3d. to 1s. 9d. per yard.

Catalogues of the above can be had at Mr. Foster's offices, or at the rooms where the sale now is, 105, Fleet street, corner of Farringdon street, and bottom of Ludgate Hill.

Omnibuses pass from all parts of the town every minute in the day. Carriages will find Farringdon Street a convenient place to stand.

GILLOTT'S PENS.

THE QUEEN has been graciously pleased to command that JOSEPH GILLOTT, of Birmingham, be appointed STEEL PEN MANUFACTURER IN ORDINARY TO HER MAJESTY, dated April 13th, 1840.

JOSEPH GILLOTT'S very superior PATENT and other METALLIC PENS may be had of all Stationers, Booksellers, and other Dealers in Pens throughout the United Kingdom.

It is gratifying to the Patentee to acknowledge his obligations to the Public for the best proof they can give him of their approbation, in the continually increasing demand for his Pens.

The number of Pens manufactured at the Works of JOSEPH GILLOTT from Oct. 1838 to Oct. 1839, was 44,654,702, or 3,721,225 dozens, or 310,102 gross; and from Dec. 1840 to Dec. 1841, was 62,126,928, or 5,177,244 dozens, or 431,137 gross.

CAUTION. All the Genuine Pens are marked in full "JOSEPH GILLOTT;" and venders are desired to note that Cards of Pens are made up in packets of 1 dozen each, and have a label outside, with a facsimile of his signature.

*** At the request of persons extensively engaged in tuition, J. G. has introduced his WARRANTED SCHOOL PENS, which are specially adapted to their use, being of different degrees of flexibility, and with fine, medium, and broad points.

Wholesale and for Exportation at the Manufactory, VICTORIA WORKS, GRAHAM STREET, BIRMINGHAM, and at 37, GRACECHURCH STREET, LONDON, under the management of Mr. Fox, from the Manufactory at Birmingham, or from any of the Wholesale Stationers in London, &c.

WARM, Vapour, Shampooing, and Sulphur BATHS, 5, New Broad street, city.—This establishment is unequalled in the kingdom in point of magnitude, comfort, economy or convenience, if such can be comprised in a suite of 12 rooms, cheerful fires, hot linen, moderate charges, cleanly and respectable male and female attendants, and any kind of Bath to be had at a moment's notice.—Dr. CULVERWELL, the proprietor, attends daily from 11 to 2. Prospectuses gratis.

DR. JAMES'S POWDER.—The pre-eminence of this celebrated medicine, and its unrivalled success as a Febrifuge for UPWARDS OF NINETY YEARS, has given rise to imitators, who rely only on the "ANTIMONIAL POWDER," of the Pharmacopœia of the College of Physicians. A most elaborate Analysis of the two Medicines was published in the Philosophical Transactions, from which it was confidently assumed that they were the same; but in a subsequent edition, the College fairly and frankly confessed, that the Powder "WAS NEITHER SO *mild* NOR SO *certain* IN ITS OPERATIONS AS DR. JAMES'S, and that it could not be administered with safety in similar doses;" and when health and life are at stake, no one surely will sacrifice to any substitute the long approved efficacy, safety, and certainty of the Original Medicine, which generally cuts short the duration of the complaint. DR. JAMES'S POWDER is prepared uniformly by Messrs. Newbery, from the only Copy of the Process left by Dr. James in his own hand-writing, which was deposited with their Grandfather in 1746 as joint Proprietor, and is sold by them in packets, 2s. 9d. and 24s., at 45, St. Paul's Churchyard, J. Sanger, 150, Oxford Street, and their Agents in most Country Towns.—The genuine is distinguished by having the name, "F. NEWBERY," engraved on the Government Stamp.

DEPARTMENT OF MEDICAL STATISTICS.

William Farr, Esq., General Register Office

ACTUARY.

F. G. P. Neilson, Esq.

This Office is provided with very accurately constructed Tables, by which it can Assure UNSOUND Lives on Equitable Terms. The Extra Premium discontinued on restoration of the Assured to permanent health. A portion of the extra premium may remain as a Debt on the Policy. Survivorship Assurances where the life in expectation suffers from disease, effected at cheaper rates than at any other office.

Similar tables enable the Society to grant Increased Annuities on Unsound Lives, the amount varying with the particular disease. Members of Consumptive Families assured at Equitable Rates. Healthy lives are Assured on lower terms than at most other Offices.

Application for Agencies to be made to the Actuary.

SILVER SUPERSEDED and those corrosive and injurious metals, called Nickel and German Silver, supplanted by the introduction of a new, and perfectly matchless ALBATA PLATE. C. WATSON, (late ALDERMAN,) 41 & 42, BARBICAN, and 16, NORTON FOLGATE, aided by a person of Science in the amalgamation of Metals, has succeeded in bringing to public notice the most beautiful Article ever yet offered, possessing all the richness of Silver in appearance—with all its durability and hardness—with its perfect sweetness in use—undergoing, as it does, a Chemical Process, by which all that is nauseous in mixed Metals is entirely extracted—resisting all Acids—may be cleaned as Silver, and is Manufactured into every Article for the Table and Sideboard.

		s.	d.
Table Spoons and Forks	per doz.	16	6
Dessert Ditto	ditto	12	6
Soup Ladles		6	6
Sauce Ladles		1	9
Tea Spoons	per doz.	5	6
Gravy Spoons		3	6

C. WATSON begs the Public will understand that this Metal is peculiarly his own, and that Silver is not more different from Gold, than *his* Metal is from all others; the Public will, therefore, have no difficulty in discovering the animus which directs the violent attacks made against him by a party who is daily suffering from the unparalleled success which has marked the progress of *his* New Plate since its introduction. C. W., unlike this *party*, courts comparison, feeling confident that the result will establish its pre-eminence. Entire Services of Plate Purchased. 41 & 42, Barbican, and at 16, Norton Folgate.

PAPER TEA TRAYS, 12s.;—a full-sized set of three, Gothic Pattern, and an infinite variety of others, up to 10 guineas a set, a set of three convex japan trays, 10s., very best London made tea urns, in every variety, from 36s. to 105s.; a dozen Ivory knives, 11s.; a dozen dessert ditto, 10s. 8d., carvers, 1s. 6d. per pair, fenders, from 6s. to 63s.; fire irons, from 3s. 3d. to 25s.; American ovens, to bake before the fire, 4s, copper kettle, 5s. 6d., copper coal scoop, 11s. 6d., iron saucepans, enamel inside, 1s. 6d. upwards, and every article in furnishing ironmongery unusually low. Quality is here the primary consideration,—hence its uninterrupted success for 50 years, and its present celebrity as one of the best and most extensive furnishing warehouses in London.

This day is published, 8vo. cloth, price 10s. 6d.

A PRACTICAL and THEORETICAL TREATISE on the Diagnosis, Pathology, and Treatment of DISEASES of the SKIN, arranged according to a Natural System of Classification, and preceded by an Outline of the Anatomy and Physiology of the Skin. JAMES LEATH (Successor to Thos. Hurst), 5, St Paul's Churchyard.

E V E N I N G S T A R.

FIFTEEN SHILLINGS FOR FOUR PENCE!!!

AGRICULTURISTS, MANUFACTURERS, MERCHANTS, BANKERS, MECHANICS, ARTIZANS, LABOURERS, &c. &c. are respectfully informed that THE EVENING STAR, daily Newspaper, price Four pence, size of the "Morning Advertiser," the "Standard," and other Daily Papers, advocates the right of all, and is Published daily at 252, Strand, London, and can be obtained through all Newsmen and Post Masters in the United Kingdom.

DOUBLE SHEET.

On SATURDAY, NOVEMBER the 12th, the Publisher of THE EVENING STAR will issue a sheet double its present size, at the usual price, one half of which will contain an entire work of 100 pages, sold at Fifteen Shillings by the booksellers, entitled the

LIFE OF GENERAL GEORGE WASHINGTON.

The work will be found particularly instructive to the public generally, as it conveys a moral lesson seldom discovered.

Order the DOUBLE SHEET of the Agents of the EVENING STAR, or of the subscriber.

As it is the object of the publisher, by this valuable double sheet, to introduce the STAR into every town in the kingdom, we ask our friends to give every possible publicity to this novel enterprise, and to induce their friends to enclose the price, pre-paid,

FOUR-PENCE,

for a copy, as soon as possible.

THE EVENING STAR is now read in every city, borough, and town of importance in England, Ireland, Scotland, and Wales.

Give your orders immediately to your Newsmen for THE EVENING STAR.

All those who wish their Advertisements to appear in the Number for the 12th of November, will cause them to be forwarded to the Office of THE EVENING STAR, 252, Strand, London, as soon as possible, addressed to G. F. PARDON.

N. C.—It is the intention of the Publisher, should the Double Sheet meet with due encouragement, to publish a similar one every SATURDAY, in order to form a complete

BIOGRAPHICAL LIBRARY FOR THE PEOPLE.

GEORGE HARRIS, WRITER & LABELLER to the Medical Profession, 15, Little Queen Street, Holborn.

G. H. most respectfully returns his thanks to the Medical Profession, and Chemists and Druggists generally, for the very liberal support he has received as a Labeller and Writer for 20 years, and begs leave to observe, that he now undertakes to fit up Shops and Surgeries in the style of elegance or neatness, and to any price; and trusts, from the great experience he has had with the late Mrs. Willats, Mr Bruce, and for the last 10 years with the highly respectable firm of Ansell and Hawke, 8, Great Queen Street, Lincoln's Inn fields, that he will be enabled to give satisfaction.

Stoppered rounds, 1s. per lb., mahogany fronted drawers 1s. 11d. each, labelling in the very best style, 3s. 6d. per dozen. Every article warranted.

PRIVATE LUNATIC ASYLUM.

TO THE MEDICAL PROFESSION.—To be DISPOSED of a FREEHOLD PRIVATE LUNATIC ASYLUM in the WEST of ENGLAND which has been Established upwards of 120 years.

Application by letter, only pre-paid, to be made to W. B., No. 1, Queen Street, Brompton.

KING'S COLLEGE.—In a respectable private family residing in one of the streets in the Strand adjoining KING'S COLLEGE, a limited number of STUDENTS are accommodated with Board and Lodging. Respectable references given, amongst which Principal Lonsdale allows his name to be mentioned.

For cards of address, apply to Mr Dickson, 167, Strand, and Mr. Edkins, 16, Salisbury Square, Fleet Street.

PRIVATE SCHOOL of MEDICINE, No. 34, BURTON CRESCENT, (being most conveniently situated for all the Medical Schools, both at the East and West End of London), for Individual and Private Examinations in all the Departments necessary for passing the College of Surgeons, Army and Navy Boards, and Apothecaries' Hall, under the Direction of Mr. T. D. HAWKER, M.R.C.S., and L.A.H., who has been successfully engaged for many years, in passing Gentlemen through their Examinations.

Peculiar Advantages are always at Command for promoting the progress of the Student, Dissections and Demonstrations, Preparations, Plates, Specimens of Materia Medica, &c.

The system adopted and carried out at this Establishment, is precisely similar to that exercised by the PRIVATE TUTOR at the Universities of Oxford, and Cambridge, success is secured to the Pupil, but he is at the same time thoroughly grounded, in the different branches of Professional Knowledge.

Vacancies for House Pupils.

A Vacancy for an Apprentice, with great opportunities.

REFERENCES.—The Editors of the POLYTECHNIC and COURT JOURNALS.

Extract from the POLYTECHNIC:—"It is not our custom to notice Establishments of this kind—but having inspected Mr. Hawker's, and known him for many years as a most successful Private Teacher, we can conscientiously recommend it to the Pupils of the Medical Profession."—Editor of the Polytechnic.

ROYAL

ADELAIDE  GALLERY.

LECTURES on CHEMISTRY, &c., by Dr. ATKIN.—Dr. Atkin commenced a Course of Lectures on Chemistry in the Laboratory of the Institution, on WEDNESDAY, October 5th, 1842, at 9 o'clock a.m., and will continue them every morning at the same hour.

The course will consist of upwards of 100 Lectures, and is intended for persons wishing to study Chemistry, either as a branch of medical education, or in its application to Arts, Manufactures, &c. The modes of examining and analyzing inorganic bodies will be shown and explained. A considerable part of the course will be devoted to organic Chemistry, &c., and a full account given of the latest discoveries by continental observers. Fee, Five Guineas.

On the same day a series of Lectures on Practical Chemistry will be commenced, in which the Pupils will have opportunities of performing experiments, applying tests, and becoming familiar with manipulation. Each practical course will comprise sixty lessons, and be given at hours to suit the convenience of students. Fee, Three Guineas.

One Course will be especially devoted to Chemists and Druggists.

Extended laboratory practice for not less than three months, at the rate of Fifty Guineas per Annum.

Assays and Analyzes conducted by the Chemist personally. Mineral Assays from 10s. 6d. to £1. 1s. each. Agricultural and other Analyzes on moderate terms.

Gentlemen wishing to carry out especial investigations, or experiments for perfecting inventions, may have the use of apparatus and the assistance of the Chemist, by applying to the Secretary.

IMPROVED ELASTIC SPIRAL PESSARY; invented by Dr CLAY, of Manchester. Registered and made only by JOHN and WILLIAM WOOD, Surgical Instrument Makers, Manchester.

This elegant INSTRUMENT has been extensively tried, and can be worn with perfect ease, allowing the injured parts to regain their natural tone and position, a circumstance not effected by any other plan. For particulars, see the Lancet, vol. 2, 1840. Braithwaite's Retrospect of Medical Journals, for 1841, and a Paper by Dr. Clay, read before the Medical Section of the British Association, assembled in Manchester, which is published in full in the MEDICAL TIMES, vol 6, 1842, pp. 329—330, illustrated with woodcuts.

A Letter signed by the INVENTOR accompanies each Instrument, without which, none can be warranted.

This Pessary can be sent by post on receipt of a Post Office order for the Amount.

PRICES: Pure silver, £2. 6s., German silver, £1.

Leeds Public Dispensary.

TWO ASSISTANT APOTHECARIES being required for this Institution, whose duties will be to Dispense and Assist in Visiting, Notice is hereby given, That the MEDICAL OFFICERS will proceed to the ELECTION, on THURSDAY the 17th of NOVEMBER NEXT. Candidates are required to attend personally at the Dispensary, on MONDAY the 14th of NOVEMBER, at Twelve o'clock, when Testimonials of Moral and Professional Character are to be produced.

Further Particulars may be known on application to the Medical Officers of the Institution, or to Mr Lee, at the Dispensary.

Opportunity will be afforded of attending the Lectures at the Leeds School of Medicine which qualifies for Examination at the Medical Board.

CHAS. LEE., Secretary.

Oct. 27th, 1842.

HORSE CLOTHS MADE WATERPROOF by the Celebrated Burmese Japan Process of NEWBERY and Co.

This Excellent Protection for that good and useful Animal, the Horse, is fast superseding every other cloth or covering. It is totally impervious to rain, does not shrink, shrivel or crack, and is very strong and lasting; the prices are moderate.

IMPROVED HORSE CLOTHS.

Horses, like ourselves, are benefitted by a clothing, which while waterproof, will not impede the free escape of perspiration.

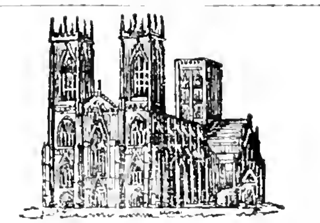
NEWBERY'S LYCOPODIUM, or ventilating process of Waterproofing is admirably adapted and may be safely applied for waterproofing the clothing of Gentlemen's Horses.

When very hard wear is required, and for common use, their Burmese Japan Canvas will be found all that can be desired, for it is at once the most impervious, tough, flexible and durable composition ever offered to the public.

No. 7, Cripplegate Buildings, Fore Street, City; 16, Pall Mall; 31, King William Street; or by post at the Manufactory, Church street, Deptford, Kent.

CALEDONIAN and CITY of LONDON INFIRMARY, 111, Aldersgate Street, for the definitive Cure of Rupture, &c., so as to enable the patient to leave off all truss wearing ever after, and by timely application in the first stage of the complaint great inconvenience may be avoided, and no truss whatever is required; the only thing of the kind in the United Kingdom.

MOSLEY'S METALLIC PENS.—The extraordinary patronage which these celebrated PENS have met with since their first introduction to the public, is a convincing proof of their decided superiority. For ease and smoothness in writing they are equal in every respect to the quill, while their great durability, combined with their cheapness, cannot fail to recommend them to the notice of merchants, bankers, and others, where time and legible writing are appreciated. Another proof of their sterling qualities is the circumstance of their being used in most of the Government Establishments, where only articles of a superior description are admitted. To guard against the many spurious imitations that are palmed upon the public, every genuine pen is stamped "Richard Mosley and Co., London." These pens are sold by all stationers and other respectable pen-dealers throughout the Kingdom; and wholesale at No. 8, HATTON GARDEN.



THE YORKSHIRE FIRE AND LIFE INSURANCE COMPANY.

Established at York, 1824, and Empowered by Act of Parliament. Capital, £500,000.

PATRONS.

The Archbishop of York.	Sir Francis Lawley, Bart.
The Marquis of Londonderry.	Sir W. R. Cooke, Bart.
Earl Fitzwilliam.	Sir W. A. Ingilby, Bart.
The Earl of Tyrconnel.	Sir Tatton Sykes, Bart.
The Earl of Zetland.	Sir E. M. Vavasour, Bart.
The Earl of Yarborough.	Sir S. Crompton, Bart., M.P.
The Bishop of Ripon.	The Archdeacon of York.
Viscount Morpeth.	Archdeacon of the East Riding.
Lord Wharncliffe.	The Archdeacon of Cleveland.
Lord Feversham.	Jno. Henry Lowther, Esq. M.P.
Lord Hotham, M.P.	G. L. Barlow, Esq.
Lord Howden, K.C.S. K.T.H., &c.	Robert Cracroft, Esq.
Lord Wenlock.	Robert Denison, Esq.
Lord Worsley, M.P.	P. Saltmarshe, Esq.
Hon. E. R. Petre.	Marmaduke Wyvill, Esq.
Sir G. Strickland, Bart. M.P.	

Actuary and Secretary,—Mr. W. L. NEWMAN, YORK.

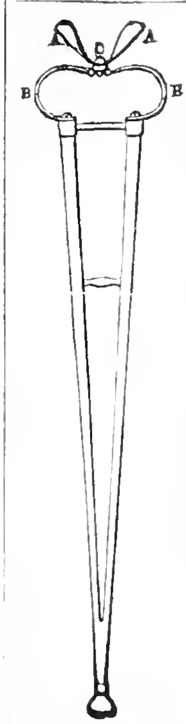
London Agent for the Life Department, Mr. Edward Henwood, 46, Watling Street.

The attention of the Public is requested to the terms of this Company for Life Insurance, and especially for Female Lives.

Fire Insurances are also effected by this Company, on the most moderate terms.

Farming Stock insured without the average clause.

Prospectuses with the rates of premium, and every information may be had at the Head Office, in York, or of any of the agents.



J. WALTERS,

ANATOMICAL MACHINIST, &c.,

16, MOORGATE ST., LONDON,

BEGS to call attention to the under mentioned of his contrivances, which have met with the approbation of the most eminent surgeons, and will be found to combine many advantages.

THE HYDRO-PNEUMATIC ENEMA SYRINGE.

This newly invented instrument is very much superior to any at present in use, on account of its simplicity, great portability, and durability. It is in itself Reservoir and Syringe, less than half the size of any others that hold the same quantity of fluid, and gives a continuous jet of any force required, and free from air.

THE ELLIPTICAL SPRING CRUTCH.

By the construction of the air pads of the springs and of the central joint, the greatest freedom of motion is allowed, without that distressing numbness of the arm produced by crutches of every other description.

THE ELASTIC LACED BANDAGES,

For Varicose Veins, &c., are light and durable, allow the evaporation to pass freely through them, and, from the thinness of the material, cause but little addition of warmth. The price is much less than that of any other equally well made. Instructions for measuring will be forwarded on application.

THE NEW HIP-JOINT SPLINT

Has been used in many cases, and can be confidently recommended as the best hitherto contrived for disease of this joint.

London: Printed and Published by JAMES ANGERSTEIN CARFRAE, at 1, Essex Street, Strand, in the Parish of St. Clements Danes, Westminster, in the County of Middlesex.—November 5th, 1842.

AGENTS: Maclachlan & Son, Edinburgh; Simms & Son, Wilmer and Smith, Liverpool; Fannin & Co., Dublin.

THE MEDICAL TIMES

A Journal of English and Foreign Medicine and Medical Affairs.

No. 161. Vol. VII. LONDON, SATURDAY, NOVEMBER 12, 1842. PRICE FOURPENCE. Stamped Edition, 5d.

For the convenience of Subscribers in remote places, the Weekly Numbers are re-issued in Monthly Parts, stitched in a Wrapper, and forwarded with the Magazines. Orders for the Stamped Edition [10s. 10d. per Half-year, Post-free in advance,] are received by any Bookseller or Newsman, or may be directed to J. A. Carfrae, Esq., at the Medical Times Office, (late Lancet Office), London.

SUMMARY.

CASES OF PERITONEAL SECTION

FOR THE

EXTIRPATION OF DISEASED OVARIA BY THE LARGE INCISION FROM STERNUM TO PUBES, SUCCESSFULLY TREATED.

By CHARLES CLAY, Member of the Royal College of Physicians, London; of the College of Surgeons, Edinburgh, and Lecturer on Medical Jurisprudence, &c. Piccadilly, Manchester.

(Continued from page 85.)

SUMMARY

From the conclusion of the first fifty-two hours to the end of the fourth day, when the wound was first dressed.

Temperature.—Kept about the same.

Pulse.—Increased in frequency, but kept soft and very compressible.

Tongue.—Kept very clean and moist.

General Surface.—Moist and Warm.

Urine.—Continued very free by natural efforts, nearly five pounds in the last forty-five hours.

Motions.—2 immediately after the clysters.

Thirst and Flatus.—Entirely absent.

Sleep.—The time passed in sleep was considerable; thirteen hours out of the last forty-five hours—or thirty hours out of the ninety-seven, from the commencement.

The last table shews the progress from the conclusion of the fourth day to the termination of the case. The item of temperature is now omitted, as unnecessary.

GENERAL REMARKS.	Sleep	Thirst	Motions	Urine	Surface	Tongue	Pulse	FROM THE CONCLUSION OF THE 4TH DAY TO THE TERMINATION OF THE CASE.
Broth from mutton ordered once in the day—a clyster to be given in the evening.	All night.	None.	None.	4 times ℥xxiv.	Moist.	Clean.	100 Very soft	Oct. 12th, 5 o'clock p.m.
Pulse less rapid, very soft—a motion had followed the last clyster, very copious.	Nearly all night.	None.	One after clyster.	3 times ℥xxi.	Moist.	Clean.	95 Very soft	Oct. 13th, 5 o'clock p.m.
Dressed the wound, all the sutures removed—wound requires but little dressing—ligatures not come away—For diet, more generous soups added.	All night.	None.	One natural in them.	Twice ℥xviii.	Moist.	Clean.	90 Soft.	Oct. 14th, ditto.
No restrictions as to diet—rapidly improving in strength—sitting up allowed.	All night.	None.	Two naturally.	Twice ℥xx.	Moist.	Clean.	85	Oct. 15th, ditto.
Wound requires little or no dressing—continues well.	All night.	None.	Two naturally.	Twice ℥viii.	Moist.	Clean.	80	Oct. 16th, ditto.
Continues well.	Slept well.	None.	One.	Frequently.	Moist.	Clean.	75	Oct. 17th, ditto.
Continues well.	Slept well.	None.	Two.	Frequently.	Moist.	Clean.	76	Oct. 18th, ditto.
Continues well	Slept well.	None.	Two.	Frequently.	Moist.	Clean.	74	Oct. 19th, ditto.
Continues well.	Slept well.	None.	Two.	Frequently.	Moist.	Clean.	76	Oct. 20th, ditto.
Considered as cured, calling only occasionally subsequently.	Slept well.	None.	One.	Frequently.	Moist.	Clean.	75	Oct. 21st, ditto.

ADDITIONAL GENERAL OBSERVATIONS.

The success of this second case cannot but be admitted as more remarkable and conclusive than the first. The advanced age of my patient, the numerous adhesions, the extensive ascitic deposit, and worn down constitution, offered but slight prospects of recovery; still the depression of her mind and the inconvenience of a burthen, accompanied with great pain, coupled with the positive assurances, that her case was perfectly hopeless, rendered even the smallest chance of life by operation very desirable. Under such circumstances, then, the proceeding was justifiable, and her perfect and rapid recovery only tends to confirm the views I have before expressed in respect to this operation. In my mind I feel convinced that in very many instances of apparently incurable ascites, ovarian disease has previously existed, which in fact is the exciting cause of the ascitic deposit. This second case, also proves the value of the simplest mode of treatment. One dose of mur. morphine immediately after the operation, two aperient doses of inspissated gall, and two clysters, being the whole amount of medical assistance, except the most rigid attention to diet prescribed, an equable temperature, and perfect quietness. Mr. Lizars attributes his success in the after treatment to timely bleeding, and certainly, I believe, there is little good to be done without it, the pulse must, however first indicate the necessity for it; in this case no blood was taken, the pulse never being otherwise than soft, and easily compressible; perhaps her advanced age might account for the want of energy in the circulatory powers; another proof of this was the remarkable fact already alluded to, that the pulse did not vary one stroke after the operation from what it was before. The tumour was freely injected with blood vessels; yet no vessels, either in the pedicle, or in any of its adhesions, required the ligature; and the blood lost during the operation was very trifling, certainly not two ounces. Throughout the case there was an extensive secretion of urine, which at all times passed without the assistance of the catheter. I did not interfere with her habit of smoking as she had been long accustomed to it, and seemed to derive a little pleasure from the indulgence. In both these cases the ligatures connected with the pedicles were brought out at the very lowest point of the external incisions, those of Mr. Lizars were (it appears from his plates) brought out about midway between the umbilicus and pubes; this is a matter of mere choice; for my own part, I fancied the ligature would interfere less with visceral movements by being brought out lower than otherwise, which was my reason for adopting it. It is impossible to reflect upon the nature of these cases without admitting how very improper it would have been to put in practice the recommendation of Mr. Jeaffreson. The adhesions and solid parts of the tumours, would have rendered such a mode impracticable; and the exposure of the viscera, with the effects of a large incision, are not more dangerous than a mere puncture without exposure, now, beyond a doubt, abundantly proved by the cases of Dr. Macdowal, Mr. Lizars, and myself. When the prejudices against the operation shall have subsided, there exists not a doubt but that it must, as a matter of necessity, be admitted as a perfectly legitimate operation, and justifiable in every stage of diseased ovaria. It is to be hoped, too, that these operations will convince surgeons that the great fatality attending many capital operations, where *the peritoneum is concerned*, consists in driving the case to extremes; by adopting various modes of relief (*which failing*) produce greater *peritoneal irritation*, than when the knife is made use of, and fatal inflammatory action is often the result. I feel little doubt in attributing many deaths,

subsequent to operations on the peritoneal sac, not to the undue interference with the knife, but to the means put in practice before the knife is resorted to, for instance, the manipulations of taxis in hernia. Take the peritoneum in its quiescent state, the knife can then be used with much less pain to the patient, and those operations, so often fatal, and if successful, so critical in their after treatment, will become seldom fatal and extremely simple in their subsequent treatment. I shall now draw my remarks towards a conclusion; perhaps they may be considered too lengthy, the importance however of the cases is such, that the omission of even the slightest particular, might be the means of leading others to wrong conclusions. For those who may not have leisure to attend to it, I have thought proper to add a statistical account of such cases as have been treated by both operations, spoken of in these remarks, and which I hope will speak volumes in favour of the large incision.

Small Incision as practised by

Dohlhoff,	Germany,	1 successful,	2 fatal.
Jeaffreson,	Ipswich,	1 successful.	
King,	Saxmundham,	2 successful,	1 fatal.
West,	Tonbridge,	1 successful.	
Phillips,	London		1 fatal.
		—	—
	Total,	5 successful,	4 fatal.

Out of the five successful cases, two, viz., one by Dohlhoff, and one by King were cut merely, there *being no tumour*, consequently no violence was done to the viscera: the cases being those of simple scalpel wounds.

The large Incision and Extirpation as practised by

L'Aumonier,	France,	1 successful.	
Dr. Smith,	Connecticut,	1 successful.	
Dr. Macdowal,	Kentucky,	3 successful.	
Mr. Lizars,	Scotland,	3 successful,	1 fatal.
Dr. Clay,	Manchester,	2 successful,	
		—	—
		10 successful	1 fatal

One of these successful cases was cut down upon, but no tumour was found, by Mr. Lizars. At the same time it ought to be stated that the fatal case (also by Mr. Lizars) had previously suffered from an attack of cholera, which, with equal probability with the operation, might be considered as the cause of death.

I have now faithfully detailed my own cases, and, as far as I could obtain them, the practice and opinions of others. I have endeavoured to shew, without prejudice to either, the comparative value of both operations. The puncturing of ovarian sacs I have not entered into, simply, because it is not a curative agency, but merely a means of temporary relief to be followed by still greater sufferings, with the certain prospect of a fatal termination. Even simple puncturing has been fatal in more instances than one. I am averse to puncturing, because it offers no hope of ultimate cure, and because at the places punctured, adhesions are effected, and by the alternate distention, and collapse of the sac, fresh adhesions are also formed in other parts.

The number of adhesions, however, can be overcome by the large incision with great ease; and experience tells me the patient may recover from the separation of them, however numerous; and that without a bad symptom even in an aged person. But such adhesions, or even a suspicion that they may exist (and I venture to say no man can tell where they are not to be met with before operation) must at once condemn the small-incision operation. Time, and a few more opportunities will settle this question, I am confident, in favour of the large incision. To have room to be enabled to see that no unnecessary mischief is done, is the true principle of the large operation. Lastly, the being enabled *to see* the state, not only of the parts contemplated to be extirpated but the connecting viscera, and that *in time to retrace our steps if necessary*, with having only the simple incision to heal again, is a circumstance that cannot attend the minor operation.

(To be continued.)

LECTURES ON CHEMISTRY.

By JOHN SCOFFERN, M.D., Lecturer on Chemistry, at the Aldersgate School of Medicine.

Having glanced casually in our last lecture at the principal theories of the voltaic battery, and having drawn your attention to some of its various forms, I left off, with a promise to investigate, when we should meet again, some of the chemical effects of voltaic electricity.

Before I do so, however, I must again caution you against being misled by the terms positive and negative, as applied to voltaic arrangements. It would seem (as I have before observed) that in a simple and compound voltaic arrangement, each being composed of zinc and copper, and acted upon by an acid, that in the simple arrangement the copper would be positive, and in a compound arrangement the zinc; because in the usual forms of such apparatus, each of these metals in turn is made to *emit* the current. But this is a mere casualty, dependent upon a convenient mechanical arrangement of the elements of the battery. Other arrangements might be employed which would make either element of the battery, at pleasure, either positive or negative, to use the terms in their common acceptation, a fact which proves, I think, that they should *not* be used. Surely the terms *emitting* and *receiving* would be more convenient, when speaking of voltaic arrangements, than positive and negative.

Having made these remarks, which seemed to me likely to prevent much future misunderstanding, we will proceed to examine the chemical effects of voltaic electricity. In the year 1800, it was discovered by Messrs. Nicholson and Carlisle, that when two wires, one proceeding from each terminal part of a compound voltaic series, were brought near together under water, the fluid was rapidly decomposed, and little bubbles of oxygen and hydrogen, its constituents, escaped; these by a very simple contrivance may be collected separately. Now it was observed that the gases in question were not eliminated from either wire indiscriminately, but that hydrogen escaped from the wire which received the electric current, or the negative wire, and oxygen from the other.

This was the first instance noticed of a body being decomposed by voltaic electricity; but other discoveries of a similar kind soon followed. It was found that certain saline bodies under similar circumstances were also decomposed, the acid invariably proceeding to the *emitting* or positive wire, and the base to the other. But the most brilliant discovery made by this agent, thus applied, was that of the compound nature of the alkalies and earths. Potash, for instance, one of the fixed alkalies, had been assumed hitherto to be a simple or undecomposable body, but Sir H. Davy separated it by the agency of voltaic electricity into a metal, called by him potassium, and the substance oxygen; of these, oxygen was liberated, as in the case of the decomposition of water, at the emitting or positive end of the battery, and potassium at the other. Precisely analogous were the results when the two other fixed alkalies, *soda* and *lithia*, were exposed to the same agency. All these were found to be metallic oxides. Encouraged by these results, Sir H. Davy proceeded to experimentalize on the earths, such as lime, magnesia, alumina, and others, to which they are more or less allied; these two, Davy proved to be metallic oxides, of which the oxygen was always eliminated at the *receiving* or positive wire, and their respective metallic radicals at the other. You may have remarked that hitherto, during these descriptions of voltaic decompositions, I have avoided using the terms *end* or *pole*, terms frequently employed in treatises on voltaic electricity, but which all, more or less, involve notions that are incorrect, and therefore improper. Every voltaic arrangement must afford some provision for a circulation of the electricity generated by it; in other words its action is in a circuit, and if this circuit be *effectually* broken, its very constitution as a battery is annihilated. If any part of the circumference of a ring were cut across, so that it no longer formed a complete circle, you certainly would not apply the terms *beginning* and *end* to the cut parts—the very words *beginning* and *end* of a ring convey an absurdity. I wish you then to be incapable of thinking of the beginning or end of a voltaic arrangement, however much the mechanical form of such an arrangement might seem to countenance the terms. I wish you moreover to remember, that although we speak of certain substances being acted upon, or decomposed, by a voltaic battery, yet those substances, in point of fact, are a part of the battery, that they are not merely acted upon or passive, but exert their own agencies in return, and correspond *with*, and are proportionate *to*, other actions taking place simultaneously in other parts of the arrangement. I am particular in mentioning these things to you thus early, because we are going presently to examine the theory of electro-chemical decomposition, as originating with Davy. Then Davy and *his* associates, think you, took care, for some reason not yet known to us, never to use the terms *end* or *pole*, as applied to voltaic arrangements, and moreover regarded the material acted upon in these experiments as forming a part of the voltaic series? Not at all. Davy and his associates did *precisely the reverse of all this*; so now I trust you will be prepared to follow me in detailing some of his experiments, and the results to which they led.

We have seen that oxygen and acids proceed, when substances containing them are decomposed by voltaic electricity, to the emitting or positive wire, and hydrogen, and bases, and metals, to the receiving, or negative wire. This result was invariable in every experiment hitherto noticed; and the more extended investigations of Davy led him to suppose that such was universal. Now why do oxygen and the acids always go to one wire more than the other?—why hydrogen, bases, and metals?—what force has voltaic electricity overcome?—why has it determined them to different sides?

Only one of these questions admits of an answer, apart from speculation. The force overcome by electricity, in either of these instances, is the force of chemical attraction, or affinity, the nature of which is not known, as I mentioned when speaking of affinity; but perhaps the very experiments under consideration will unveil the mystery. Thus thought Davy. Before I point out to you the leading points of those doctrines which Davy ultimately espoused, from a consideration of these results, let me call your attention to one of the most universal and best marked properties of electricity, as developed by the machine, attraction and repulsion. You are aware that any light body (say a pith ball) when electrified positively, will attract towards itself any other pith ball electrified negatively, and brought sufficiently near to it. This is universal, and it is a result just as universal, that when the pith balls have touched each other, they separate again. The former of these two phenomena Davy had in his mind when he speculated on the causes of voltaic decomposition, the latter by some unaccountable chance he happened to forget altogether; but let us now examine his celebrated electro-chemical theory. Davy imagined that the cause of chemical union was the agency of opposite electrical energies. He imagined, for instance, that the atoms of hydrogen were universally positive, and those of oxygen universally negative, hence, under propitious circumstances, they would approach each other, and unite, as in the case of the oppositely electrified pith balls; so far the analogy is good; but why they *remained* united, Davy's theory cannot afford any satisfactory reason; he assumed, however, this to be occasioned by a species of aggregation. Be this as it may, he attributed chemical union to the particles of different bodies being in opposite electrical states, and it follows, as a deduction from such a theory, that the elements of such a compound must necessarily be separated, if exposed to stronger electrical agencies than their own. Suppose, for example, that oxygen and hydrogen are united together in the fluid water, with a force equal to the sum of 2 and 2, or 4, being the amount of their own electrical energies. These two elements

should, theoretically, be capable of separation by a force equal to the sum of 3 and 3, which we will assume to be that of the wires,—*ends* or *poles*—as Davy termed them, of a voltaic arrangement. You will not fail to remember, then, that the assumption of chemical attraction being the result of opposite electrical states of the combining molecules, was the most prominent part of Davy's electro-chemical theory; from which it followed, as a matter of course, that all chemical compounds should be capable of decomposition into their constituents, provided we could act on them by a sufficient amount of opposite electrical forces.

Necessarily connected too with this theory, is the hypothesis of the terminal wires, being attractive agents, each soliciting those molecules of a compound which were in an opposite electrical state to its own; on which supposition, the terms *poles*, as applied to such wires, were not improper. Now however fascinating a theory may be, however well it is capable of embracing one class of facts, however great the name of its originator, we must not scruple to see how it stands the test of collateral scrutiny. Let us then try the celebrated electro-chemical theory of Davy by this tribunal. First, then, can its leading assumption, that all bodies which unite chemically are in opposite electrical states, be verified? Selecting the elements of water as our example, can it be proved that oxygen is endowed with innate negative, and hydrogen with innate positive qualities. As our most delicate instruments fail to recognise this, then why assume it?—you may ask. Because without this assumption, (Davy would have said) no rational explanation of voltaic decomposition can be given. But *this* is not rational, as we shall find. I have already pointed out the fact that the parallelism between the cases of the oppositely electrified pith balls, and the presumed oppositely electrified molecules, is not maintained. Davy imagined that another force came into operation; then it should be equally as active in the opposite case,—as of the disunion of molecules. But here we find Davy's theory of the agency of voltaic electricity just as much at fault. The positive wire *attracts* the negative oxygen, the *negative* wire the positive hydrogen; he assumed then each of these substances as *liberated*, whereas in order to be consistent with the other part of the theory, each ought to unite with the metal which attracted it, forming other chemical compounds, because the *other* force assumed by Davy as succeeding electrical attraction in the former case, should be equally applicable to this.

Then what is the result of all these discoveries of the weak points of Davy's theory?—you will ask me. Why that it is incorrect in its details. Ar not the particles of all bodies which unite chemically in opposite electrical states? It seems not. At all events we cannot prove it. Do you discard this theory without offering another?—do you deny the agency of electricity altogether in promoting chemical union? What a pity to annihilate a theory so brilliant—so apparently in accordance with many facts. Is it not possible we judge it too hastily, and have not yet thoroughly comprehended it? These, gentlemen, are, I know, amongst your thoughts. Let me answer these questions as well as I can. The authority of no name, however great, will warrant us in maintaining a theory whose tenets are proved to be incorrect; we have no better theory to offer, which proves our sincerity in rejecting this. We do not deny the agency of electricity in promoting chemical union, or *vice versa*; indeed, we can prove that chemical and electrical actions are always concomitant, and *proporti nate*; probably they may stand in the light of cause and effect, but this we cannot prove. In short, if we can summon humility enough to own it, we must say that chemical and electrical agencies are mysteriously associated, but how—*we cannot tell!* In my next lecture I shall point out to you certain other facts, relative to voltaic-chemical decomposition, altogether irreconcilable with Davy's theory, which, for the most part, were discovered by Dr. Faraday, and the importance of which have added another laurel to his brow. This philosophic candour compels us to see the very simple and beautiful creation of Davy dismembered and destroyed. A being of much loveliness, though frail, from which the enchanter's promethean fire darted forth to blind men's judgments, or warp them to it; will. But the enchanter is now dead, and his creature no longer able to maintain its sway, has fallen.

LECTURES ON THE ANATOMY AND PHYSIOLOGY OF THE NERVOUS SYSTEM.

By Professor OWEN, F.R.S., &c.

We now finally come to consider the characters and progressive advances of the brain, in the mammiferous class of animals, where it reaches its highest development in man. In no other class of animals is the series of steps by which the organ mounts, as it were, to perfection, so extensive,—in none is the contrast between the highest and the lowest condition of it so great.

In the preceding classes of oviparous vertebrated animals, the marked and most tangible inferiority of the brain has been rather the transverse connecting apparatus than in the relative proportion of the cerebral hemispheres to the entire body. We have been able to trace, in birds, filamentary anterior and posterior commissures, and likewise a soft commissure:—we have seen in them a fornix, but of the corpus callosum, or great commissure, as it is termed, there has been no trace.

The mammalia, in which we might expect to find the lowest condition of the cerebral organs, are those that most resemble the ovipara in their mode of generation, and in the limitation of their intelligence. In the carnivorous marsupial animal, the Dasyure, you observe the brain to consist of the same exterior masses as in the crocodile; and these masses succeeding each other singly, or by pairs, in the same linear series. The spinal chord, expanding into the medulla oblongata, there supports a small cerebellum transversely folded, as in birds, but with rudimental lateral parts, or hemispheres. Anterior to the cerebellum, are the optic lobes, or nates, and in front of these lie the cerebral hemispheres, equally smooth and devoid of convolutions. The ventricles of these hemispheres present, however, large and conspicuous hippocampal prominences, anterior to which are the small corpora striata. The medullary fibres of the fornix are, like the hippocampal, more developed than in birds, and form a transverse commissure, uniting the hippocampi, as well as a longitudinal commissure connecting the same parts with the anterior lobes. There is a large, round, anterior commissure, many of the fibres of which connect together the olfactory lobes—those prominent masses anterior to the hemispheres. The supra-ventricular masses of the cerebrum have no transverse commissure, no corpus callosum. This low condition of the brain characterises all the marsupial and monotrematous mammalia; i.e., all ovoviviparous or implacental mammalia.

But there are grades of development in this section of the class. Thus, the wombat and the kangaroo have a few simple foldings of the cerebral substance. The hemispheres of the cerebellum are likewise, in these, more developed, and also possess pedunculate appendages. That broad band behind the optic lobes, in birds, has become narrower transversely, thicker in the vertical direction, with a slight superior convexity, and a median longitudinal division, forming the second pair of bigeminal bodies, or the testes. But this state of development can scarcely be recognized in the Ornithorinus, which differs little from birds in this respect. The testes are first clearly developed in the Marsupialia.

At first sight, the brain of the rat, the rabbit, or the squirrel, would seem to be inferior in organization to that of the Echidna, or kangaroo; but if you slice off a thin layer of the cerebral hemispheres, you will expose a broad and well-developed corpus callosum, beneath which is the hippocampal commissure, together with the anterior, posterior, and soft commissures. All the parts of the connecting apparatus of the brain are now established, and henceforth only differ in relative size.

The cerebral hemispheres progressively increase as we pass from the orders rodentia, chiroptera, and edentata, to the carnivora, the ruminants, the pacaderms, the quadrumena, and the cetacea, to man. The extent of the superficial vascular cineritious matter of the hemispheres is increased in the same gradation, chiefly by the progressive number, depth, and complications of the folds and convolutions.

A symmetrical arrangement, more or less regular or complex, can always be traced between the foldings of the two hemispheres, and the more regular in proportion to the simplicity of the convolutions; the foldings of the cerebral substance follow likewise, both in the embryonic development of a complex brain, and in the progressive permanent stages presented by the mammalian series—a regular determinate law; some convolutions being more constant than others, and these being traceable through the greatest number of brains, and recognizable even in the human brain, where at first sight they are obscured by so many accessory convolutions.

[The lecturer then demonstrated, in a considerable number of prepared brains of different animals, and in a large series of diagrams, in which the corresponding convolutions in the brains of different animals were marked by the same colours, the facts establishing this important generalization.]

With respect to the optic lobes, these appear to undergo an arrest of development in the mammalian class; or, in other and truer words, they maintain their ordinary relations of size with the optic nerves and visual organs. In the ruminants, which have large staring eyes, the optic lobes, or nates, are larger than the testes, especially in the giraffe. The testes, which seem to be developed in relation with the presence and large size of the lateral parts of the cerebellum, do not present the same variation of size as the optic lobes, and, consequently, have a larger proportionate size in the carnivora, than in the ruminants. In all mammalia, the optic lobes are solid.

The cerebellum increases in importance chiefly by the preponderence of the lateral masses, which conceal the median and vermiform processes in the cetaceous, quadrumenous, and human brains. The pons varolii, like the posterior bigeminal bodies, coexists with the lateral hemispheres of the cerebellum, and presents the same ratio of development. It is, consequently, another peculiarity of the mammalian brain. The fourth ventricle is no longer continued into the cerebellum. The third ventricle continues to be connected, by an infundibular process, with the pituitary gland; but the pineal gland, which is solid and much shrunk in size, is now attached by two pedicular processes to the thalami. The lateral ventricles are continued forwards, in most of the lower mammalia, into the substance of the olfactory bulbs.

As the cerebrum increases in height, the corpus callosum becomes progressively separated from that part of the fornix constituting the hippocampal commissure, with which, however, it is connected by a thin median vertical curtain, called the septum lucidum. This consists of two parallel walls, including a cavity called the fifth ventricle, which only exists in the higher mammalian orders.

The cerebral hemispheres progressively augment in length, cover first the optic lobes, then the cerebellum, and in man project beyond the cerebellum. Some birds have heavier brains in proportion to their light bodies than man. Some mammalia, as the whale and elephant, have absolutely larger brains than man, but no animal has so large a cerebrum in proportion to the spinal chord and nerves.

The lecturer then adverted in feeling terms to the severe and irreparable loss which science had recently sustained in the great physiologist Charles Bell, to whom the world was indebted for the deepest insight into, arising out of the most brilliant discoveries of, the nervous system, and concluded by expressing his thanks for the kind and patient attention with which his illustrations of that part of the Hunterian museum relating to the nervous system, had been received.

ROYAL COLLEGE OF SURGEONS, LONDON.

List of gentlemen admitted members on Friday, Nov. 4th, 1842.

H. Challinor, B. K. Johnson, J. Thompson, C. E. Prothero, W. Higgins, H. Marder, E. Jay, A. Ebsworth, R. B. Walcott, W. H. Hay, R. Jones.

SECALE CORNUTUM.

To CHARLES CLAY, Esq., M. D.

SIR,—Until the 1st of this month I had not seen a number of the MEDICAL TIMES,—consequently, have not, as yet, seen your remarks on the secale cornutum in the number for Sept. 3d; but, from the letter addressed to you by Mr. J. Ridout, I was almost induced to make a few observations prior to your answer to the enquiry contained in your extract of the letter, and which has appeared in the number of last week. For my own part I have great confidence in the ergot, and have tried it in tincture, powder, and decoction, and of the three most decidedly prefer the latter. It is now rather more than fourteen years since I first commenced using it, and, like many others who had preceded me, I fell into the error of administering it at periods when the uterus was not in a fit state for its exhibition; by which means I several times had the mortification of finding that a labour which might have gone on well (had I kept the ergot in my pocket and allowed Dame Nature to have her own will) was converted into one of a tedious and protracted kind, and I had the penance of additional hours of anxiety and watching, besides putting my patient to a great deal of unnecessary pain. I believe some practitioners are too apt to exhibit the remedy solely with a view to get away from their patients as quickly as possible, and frequently, by an untimely administration of it, frustrate their intention, and, in addition to a protracted labour, meet with an hour glass contraction and retained placenta. Years of experience have, I hope, given me wisdom in that respect, and I now place the greatest reliance on its virtues, and when *recently* prepared and *judiciously* given, it seldom fails to gratify the practitioner by the fulfilment of his wishes. The plan which I have for some years adopted has been, to have some *fresh* and *finely powdered* ergot put in a *closely stoppered bottle* containing three doses of the medicine, and, as the bottle is *graduated*, I have no difficulty in taking out the proper dose (2 scruples) which I boil for about the time you name (five minutes,) and exhibit *not only the decoction but the powder also*, by which means I think its virtues are more fully obtained, and, as the powder is so very fine, it is swallowed without annoyance to the patients. I generally prepare but one dose at a time, in order that the whole may be taken, and where I have expected it probable that a second might be required, I have prepared it shortly after giving the first; I therefore agree with you, that there can be but very little time lost, if any, in preparing the decoction, and, however urgent the case, such preparation appears most suitable for exhibition. In general, practitioners in the country are indifferent as to the manner in which they keep the ergot; some allowing it to remain in paper and in a situation exposed to damp, by which means it is deprived of its activity, and when it most is required too often leads the medical man to underrate its virtues as a remedial agent in obstetrics. Your mode of keeping the doses in pieces of sheet lead offers a hint to many practitioners, who no doubt will take advantage of it, particularly those who have been in the habit of carrying it about in the waistcoat pocket in no other covering than that of paper.

I am, Sir,

Your obedient servant,

HENRY GELLWOOD.

[illegible]

CAUTION TO MEDICAL MEN.

To the Editor of the 'Medical Times.'

SIR,—A few days ago a very fine man, (Scotch man, (save the mark!) called upon me, and after introducing himself as an invalid from India, who had just returned, and in fact disembarked only a day or so previously, begged I would undertake his cure. "I live close by," says he, with a winning, domesticated sort of familiarity; "over there;" says he, pointing with a ready thumb, somewhere toward the North Pole. I wish I knew exactly where. A policeman, I should tell you, called a day or two before, to warn all her Majesty's loyal medical and chemical subjects of a *youth man* going round with a sprained thumb to get advice, who, when the doctor's back was turned, contrived to use the fingers at any rate, and quietly pocketed any thing worth his while. Did you ever know the like? We so abound in silver and gold, and precious stones; there is such a plenty amongst us!

However, I eyed him narrowly in consequence, and observed, that his countenance was exceedingly fair to look upon, bless him! but I said nothing. I fetched him a chair, and planting it secundem artem right opposite the perineum, prevailed on him to be seated where he was without going into my surgery. To make a long story short, sir, I nailed him there till he took his departure; I engaged to prepare the necessary medicine for his complaint, an alleged tightness—where do you suppose, sir? Not in his head, nor yet in his belly; but, in his chest, but he never returned, though he promised faithfully to come for the physic as soon as he came back from the Docks, where his luggage and money, indeed, all his earthly treasures, were. The design of this, is, in case you think with me this youth was, and is, and wished to be a rogue, that you might warn all our society to keep the overflowing wealth, with which we are so grieviously afflicted out of the way of all Caledonians:

——— quanquam dorcis lentes.

He is a very fine man, taller than myself, and that's, speaking very highly of him, has a very sweet countenance, sandy hair, and wears mustachois.

I have the honor to be, sir, &c.

B.

P.S.—Pray sir, can you tell me which do, Parr's Pills or Cockle's (or if any of the rest of them be better) bring on miscarriage the sooner: the nursery, and other maids all about here use them so much that they smell to me exceedingly suspicious.

London, Oct. 26, 1842.

CURE OF DEAFNESS, PRODUCED BY ENLARGEMENTS OF THE TONSILS.

By WILLIAM THORNTON, Army Surgeon, M.R.C.S.

(For the 'Medical Times.')

Aug. 5th, 1842.—Miss P., a young lady, 11 years old, residing in London, consulted me on account of *deafness*. Very delicate state of health, and her general appearance such as to indicate a taint of scrofulous deitheses;—has been deaf about four years, in consequence of measles. Upon examination of the meatus externus of the right ear a purulent discharge, very offensive and the external thickened, the meatus dry and some hardened wax, which was removed by syringing into the ears. The membrana tympani of both ears healthy—could only hear my watch at two inches from each ear. On examining the fauces, found the tonsils very much enlarged and extending so far towards each other as to be within a line of their touching.

They felt hard to the touch, it appeared that she suffered about four years before from measles and inflammatory sore throat, upon recovering, she became gradually more and more deaf, in which state she has continued ever since. I prescribed friction with ung. hydrarg. iodidum, upon the external fauces, and a solution of zinc applied to the walls of the meatus and argent. nitrat. applied to the tonsils. Decoct. Sarsae. concentrated with potassae iodidum, internally; aperient powders taken twice a week. By persevering, under this treatment, with iodidum potassae, and the use of lunar caustic the tonsils recovered their ordinary size, her hearing function daily improved, and is now so acute and perfect, that she can distinguish my watch at three yards. I merely look forward to a certain change in the economy of the female constitution, which, when it occurs, I have not the least doubt, will bring with it a perfect cure of the tonsillary tumours, and that the hearing will continue in its perfect state.

The tonsillary enlargements inducing deafness, by interfering with the integrity of the Eustachian tube, and keeping up morbid condition of their and the tympanal cavities, is from its position often more palpable to the touch than the eye. For this reason the surgeon should always examine the tumours with his finger, &c.

P.S.—Cured in the course of a month.

31, Baker street, Portman Square,
7th November, 1842.

CURABILITY OF CONSUMPTION.

To the Editor of the 'Medical Times.'

SIR,—Having perused, in your excellent publication, several interesting cases of consumption, cured, contrary to the opinions entertained by the late Dr. T. Davies, who prescribed for them, permit me to add to the number two others, no less interesting than those which you have already given.

The mode by which recovery was effected in the first of the instances I am about to adduce, you will agree with me, was extraordinary—and even unprecedented; for it was occasioned by the suicidal attempt of the patient to deprive himself of life by cutting his own throat. The second is a case where a deposit of tubercles, situated over the third and fourth ribs of the left side, was liquefied; and, the breast becoming simultaneously inflamed by sympathy, the matter, from both sources, formed for itself a passage into the cavity, which the above named physician, and Dr. Ramadge had ascertained to exist on the summit of the left lung. Proceeding with the first case:

William Bell, aged 52, coach-maker, entered the Infirmary for Diseases of the Chest, as an in-patient, on the 11th November, 1837, labouring under symptoms of catarrhal asthma, which had existed for some years, but which, until a short period before his admission, did not prevent him from following his daily avocations. He mentioned that in 1827, he had had the advice of Dr. T. Davies, whilst labouring under a severe cough, perspirations, hæmoptysis, &c., and, after an examination of the chest, he was pronounced consumptive. A short time previous to receiving this intimation, he had been induced to risk his entire savings upon a prize fight, he having himself been a pugilist, and scarcely had it been announced that a vital organ was attacked by a formidable disease, before his fortune also received a shock by the defeat of the party on whom he had betted, and the consequent total loss of all his property. The event was, he committed the act of desperation before mentioned. This attempt to destroy life became the means of prolonging it for ten years, for, by a series of phenomena, the consumptive symptoms were thereby dissipated.

Soon after this he recovered by surgical aid, and it became his practice to conceal the mark of his wound with a piece of flannel. When Dr. Ramadge, in spite of the patient's ingenuity, discovered the cicatrix, and thus became acquainted with the fact of his having attempted suicide, he found, on examination, that, in breathing, when the patient *inspired*, a slight protrusion took place where the wound had been—which was between the first ring of the trachea and the cricoid cartilage; and, that in the act of *expiration* a small portion of the anterior part of the circle of the former, passed within that of the latter. The impeded expiration, the result of the obstacle just mentioned, caused, in process of time, the lower lobes of the lungs to be exceedingly enlarged, which was indicated by auscultation, as well as by an ocular inspection of the chest. Beneath and above the clavicles there were, however, the marked depressions, such as we find in phthisical persons. The action of the heart having been interfered with by the emphysematous state of the lower lobes, and displaced by the highly voluminous condition of the inferior lobe of the left lung, he became dropsical, and entered the Infirmary as an in-patient. After various remedial attempts to relieve the gorged state of the venous system, and the visceral disorders, its never-failing consequences—aggravated not a little by former habits of intemperance, he succumbed to internal effusion.

Dr. Ramadge in the early part of the treatment tried to render the expiratory powers more effective by the mechanical process he so successfully employs in establishing the wholesome relation between inspiration and expiration, or, in other words, in bringing about the natural proportion

that should exist between the windpipe and the lungs. But, in this case, there was a physical impediment, which no skill nor contrivance could overcome, for the first ring of the trachea was constantly standing in the way of the expired air.

Dissection of the body a few hours after death, shewed the upper lobes of the lungs to be contracted, indurated, and studded with innumerable tubercles of various sizes, generally small, and semi-transparent when divested of the black pulmonary matter surrounding them. Cicatrizations of different forms were therein observable, and the investing membrane of the tuberculated summits was thickened, partly cartilagenous, and adherent throughout to the opposite serous surface. The other lobes of the lungs were hypertrophied and emphysematous in the highest degree. The alteration noticed in the contour of the chest is easily accounted for by the condition of the inexpansible summits of both lungs, and the greatly enlarged state of the vesicular structure everywhere else.

This is an instructive case, as it illustrates the correctness of the view that whatever serves to expand the lungs, removes the tendency to form tubercles, and alters entirely the scrofulous diathesis. Had the patient lived, the greater portion of the tubercles found on dissection would have disappeared by absorption. After the manifestation of catarrhal asthma, all the phthisical symptoms had disappeared.

To come to the second case:—Mrs. Levi, residing in Bevis Marks, and the mother of a large family of young children, was, in the early part of the summer of 1838, visited by Dr. T. Davies and another physician, at the request of Messrs. Canstat and Dyte, her usual medical attendants. For some months she had been troubled with severe cough, purulent expectoration, hectic fever, and the other external signs of consumption. Her chest, which had undergone much contraction, was stethoscopically explored by the above-named physician, and pronounced to contain a cavity of no small extent in the superior lobe of the left lung. At this period a flattish substance of irregular form, between two and three inches in its longest extent, and which, from the absence of uneasiness, attracted but little attention, appeared superiorly to the upper circumference of the left breast, and adhered firmly to the muscles over the third and fourth ribs. The eventual occurrence of pain hereabouts, and the phthisical symptoms having increased, notwithstanding a change of air had been tried, induced Messrs. Canstat and Dyte to call in Dr. Ramadge. Accompanied by them, he saw her at Greenwich; and, after satisfying himself that, besides the constitutional symptoms of consumption, she had disease in the summit of both lungs, and a well defined excavation, as previously ascertained, he opined the indurated mass on the exterior of the chest to be a tuberculous deposition.

Having prescribed for the most urgent symptoms, and advised inhalation, with a view to defeating further contraction of the chest, which, from long experience, he knew would be followed by fresh crops of tubercles in the lungs, as well as the dangerous secondary affections, such as diarrhœa, ulceration of the larynx, &c. which so frequently follow the descent of the disease into the inferior lobes, he pointed out the possibility of a solution of the exterior tuberculous mass taking place. At the expiration of more than a month the attendance of Dr. Ramadge was again requested. During his absence the tuberculated mass liquified, and caused a sympathetic inflammation of the entire of the left breast, terminating in suppuration. —To relieve the painful distention, and allow the escape of matter, a puncture of the breast was proposed, but the courage of the patient failed, and a postponement to the following day intreated.

The same night, under a sense of great difficulty of breathing, she felt something to pass into her chest. This was instantly followed by uncontrollable cough, and an abundant discharge of fœtid expectoration. She continued coughing and expectorating, almost unceasingly, for ten hours, and brought up in this time more than two quarts of pure pus. Regretting the result of her opposition to the lancing of the mamma, she willingly submitted the next day to having it performed by one of the surgeons of Guy's Hospital. As soon as an incision was made near the nipple of the breast, a great quantity of matter, followed by air, rushed through the opening. The air came from the cavity in the top of the left lung, into which two quarts at least of puriform matter had spontaneously burst from the outside of the chest.

Two days after the surgical vent had been given, Dr. Ramadge carefully explored the chest, and explained that the air, with some of the matter, emanated from the cavity whose existence had before been announced. It was singular to witness how, at the will of the patient, the aerial fluid escaped from the wound with a hissing noise! In a few weeks she ceased to discharge from the mamma any kind of fluid; the respiratory murmur was considerably augmented, and the presence of a cavity no longer discernible. She has since had two children, enjoys good health, and, owing to the disease disappearing in the summer season, she is without any catarrhal complaint whatever. Dr. Ramadge has had leave from the family to introduce some foreign and other medical men, in order that they might be satisfied of the completeness of the recovery.

This extraordinary and interesting case recovered in consequence of the free communication between the surface of the body and the cavity of the left lung, which, whilst it allowed the free escape of the air from the cavity, permitted a general enlargement of the pulmonary tissue to take place, and, in this way, obliterated the cavity.

DISCIPULUS.

REMARKS ON THE EXCITATION OF THE ORGANS DURING SLEEPWALKING.

By T. S. Prideaux, Esq.

DURING my first successful experiment in mesmerism in October, 1841, my attention was excited by observing that some passes opposite the anterior part of the head, were followed by a fit of laughter, and in my notes made after the sitting, I inserted the two following queries, "Can individual cerebral organs be mesmerised?" "Did the laughter proceed from my mesmerising the head in the region of hope, ideality, and wit, or was it the result of the laughter I had just been indulging in, from seeing the insensibility of the patient to pricking, &c."

During two or three subsequent sittings, I made several attempts to excite individual organs with but very partial success; on one occasion a fit of crying followed my operating upon adhesiveness, the patient saying she was crying about her friends, but as during the sitting she had in imagination been present with her brother at sea, whom she had not seen for some years, I did not feel at all satisfied that the crying was the result of my operating on adhesiveness.

About this period circumstances led me to form the conclusion, that the power of reading the thoughts of the operator, is a faculty much more easily developed in the mesmeric patient than is generally supposed, and from this moment, I lost all confidence in any result I might produce by acting on the organs, considering it impossible to assure myself that the phenomena manifested, were not the result of a species of acting on the part of the patient, and I laid aside the enquiry as one which though most worthy of investigation, could only be satisfactorily prosecuted, by an operator and patient, both ignorant of phrenology, and having no *preconceived ideas* as to the phenomena to be manifested.

The publication of the experiments of Mr. Mansfield and Mr. Gardiner, in this country, and Dr. Buchanan in America, induced me again to direct my attention to the subject, and the result is that from the extreme vividness with which some of the faculties are manifested, but more especially from the fact of feeling being capable of being restored to activity, and again paralyzed at pleasure, I have come to the conclusion that the phenomena cannot with probability be referred to acting, and I now feel bound to avow my belief in the power of the mesmeriser to excite in certain cases, special organs in the patient. This being granted, it becomes a question of absorbing interest to the phrenologist, whether this new agent can be made the means of extending the boundaries of his science,—by more accurately defining the limits of the organs at present known, and discovering the localities of new ones.

The circumstance that by placing a finger over the seat of an organ and willing to excite it, the organ becomes active, was certainly calculated to excite the most sanguine expectations, but a further investigation of the conditions under which the phenomena take place, leads I fear to the conclusion, that Nature is more chary of her secrets than to allow them so easily to be wrested from her, and that no such royal path to knowledge lies open to us. Calling to mind the fact that in many cases the mesmerizer possesses the power of putting parties "en rapport" with his patient by the word of command, I was induced to suspect that volition had much more to do with the excitement of the organs, than the application of the fingers to their surfaces, and experiment soon convinced me not only that it was not necessary to touch the seat of an organ to excite it, but that it might be excited without touching the head at all by a simple act of volition.

Without then either denying, or admitting, that faculties may be excited with greater facility by contact with their surfaces, than by an act of volition alone, I think I am warranted in asserting, that the mere fact of their being capable of being excited at all, without any contact, or operation directed towards their seat, is sufficient to invalidate any evidence in support of the localities of organs drawn from such a source.

Briefly to recapitulate the conclusions at which I have arrived, they are.

That special organs of the patient are capable of being called into action by the agency of the mesmerizer. But that as these organs are capable of being excited, not only by touching their seat, but by touching any part of the head, or even by a simple act of volition, without touching the patient at all, no conclusive evidence can be drawn from such experiments as to the locality of the cerebral organs, and that though the operator, by an act of volition, can, on certain occasions, and in certain patients, excite a discriminate faculty at pleasure, we have no good ground for concluding, that by operating on a part of the head, the function of which is undiscovered, and willing to excite the particular unknown faculty attached to it whatever this might be, such unknown faculty would be called into action, and its discovery effected.

CALCULI ESCAPING THROUGH THE PARIETES OF THE ABDOMEN.

To the Editor of the 'Medical Times.'

SIR,—The following particulars of a case of biliary calculi escaping through the parietes of the abdomen are, I think, deserving a place in your valuable periodical.

Mrs. J., a widow about 50 years of age—the mother of several children, after enjoying excellent health for a number of years, while assisting at a large dinner given at her hotel on the 1st March, 1841, without any premonitary indication whatever, was suddenly attacked with a violent pain in the right hypochondrium, extending to the clavicle and top of the right shoulder, with other symptoms of hepatic derangement. Thinking these arose from flatulency, she took a little spirits and warm water and went to bed. The pain, however, continuing, she sought medical assistance, and notwithstanding the application of blisters and leeches, and the exhibition of the various remedies adopted in affections of the liver, she got no better. At length an evident fluctuation was discovered just below the last floating rib immediately over the original seat of pain, and ultimately, an abscess formed and burst externally, discharging a quantity of impure pus. On the 1st September following, a small calculus appeared in the orifice, and in a few days afterwards several others emerged, so that up to the present period above 150 have escaped, one of which I enclose for your inspection. The sinus still remains open, and calculi varying from the size of a millet seed to that of a small nut, continue to be discharged. Her general health does not at all appear to suffer, though before every fresh es-

capement of calculi severe, pains are felt over the region of the liver.

If you get the specimen analyzed, I should feel obliged by your publishing an account of its component parts. They are of precisely similar appearance.

I am, Sir,
Yours obediently,
W. THOMAS,
Surgeon.

Pembroke Dock, South Wales,
28th, October, 1842.

THE MALPRACTICE OF MIDWIVES.

(To the Editor of the 'Medical Times.')

SIR,—From the fearless and just manner in which you advocate the dignity and rights of the profession, while certain magnodipment doctors would be cutting us up in ten thousand pieces, like a Chinese mandarin convicted of high treason, I beg to solicit a corner of your valuable paper, in order to, expose, as fully as I may be able, a system of quackery more dangerous to the victims than that of St. John Long, or the very celebrated president of the British College of Health—Mr. Morrison of vegetable notoriety. The evils to which I allude are the malpractices of female accoucheurs, *alias* midwives. The case in point to which I advert happened in Aberdeenshire about two months ago; and the particulars of which have been communicated to me by a professional friend residing in that part of the country.

A married woman was, after the ordinary period of gestation, seized with parturient pains and the common symptoms of labour, which progressed favourably for a period of twelve hours, at the end of which a healthy living child was born,—and so far all was well; no professional assistance being required. A female accoucheur had charge of the case, and this woman, finding at the end of half an hour that the attachments of the placenta had not separated from the interior of the uterus, introduced her hand per vaginam, and forcibly pulled away the whole mass; the consequences of this violent proceeding was immediate prolapsus uteri. The rectum did not escape its share of the violence; and the poor woman, in addition to prolapsus uteri, has ever since laboured under prolapsus ani. It is now two months since the period of parturition, and she was found in the above state by my professional informant about two days ago.

The audacity of the *soi disant* female accoucheur is not so much to be wondered at, as the pusillanimity of the profession in not judiciously exposing the errors of ignorance on the one hand, and those of credulity on the other, for the benefit of the public. The north of Scotland, perhaps more than any other part of the island, swarms with female accoucheurs of the above stamp, who go forth upon the public, having their craniums pedantically illuminated by six weeks attendance on midwifery lectures, given in some provincial school to the slow-timed tune of three in the week. I am informed also that no professional man in any small country town in Aberdeenshire dare fall out with these female charlatans, without risk of suffering in reputation and professional emoluments; this is petticoat government with a vengeance! and proves, without doubt, that there are many old women in the profession who wear breeches. Sir, when shall we obtain those salutary reforms of the profession for which the more manly portion of it has been struggling, and the more prejudiced part opposing, for these last ten years; if we be afraid of exposing, for the sake of the bread and butter which so many of us unworthily consume, the ignorance, the audacity, and contemptuous presumption of a set of females practising without licence or professional skill. So long as the different schools of this realm are endowed with different privileges, and the members of one are favoured in comparison with those of the other, and so long as a jealousy exists amongst us as individual practitioners, so long will it be easy for quackery to prolong her dynasty, and reap the golden fruit of our dissent. The profession seems, as yet, ignorant of its real interests; and while we are squabbling amongst ourselves, the enemy is taking the advantage. Each corporate body is struggling to support its ancient, and even to acquire additional privileges; looking after the benefits of a part, whilst it should endeavour to secure the interests of the whole. We would do well to imitate the states of ancient Greece, when a foreign enemy threatened invasion of their sacred territory, to forget, for a time at least, all private animosities and turn out to a man, in order continually to apply to the legislature, until we shall have procured a bill that shall eradicate at once and for ever, the whole system of quackery, whether it be male or female, from the soil.

I am sorry to be under the necessity of animadverting so severely upon any portion of the sex; but when one part of them becomes the victims of another, it behoves every one who is cognisant of the fact, to interfere and espouse the inquiry,—in order that the public at large may see their true interests in employing properly qualified persons in any medical capacity whatever.

I am, Sir,
Your humble and obedt. servt.,
WILLIAM SMITH, Surg.

BACHELOR OF MEDICINE.—SECOND EXAMINATION. 1842. Nov. 7, 8, & 9.

GENERAL PATHOLOGY, GENERAL THERAPEUTICS AND HYGIENE.—*Examiners*, Dr. Billing and Dr. Tweedie.—1. Describe the local phenomena of inflammation, or the changes which take place in an inflamed part. Give an outline of the essential nature of inflammation.—2. State the indications to be kept in view in the treatment of dropsy.—3. Describe the specific effects of the emanations arising from stagnant water on the human body; and mention the measures best calculated to counteract their pernicious influence.—4. Translate the following passage into English.—At vomitus, ut in secundâ quoque valetudine sæpe necessarius biliosis est, sic etiam in his morbis, quos bilis concitavit. Ergo omnibus, qui ante febres horrore, et tremore vexantur; omnibus, qui cholerâ laborant; omnibus etiam, cum quâdam hilaritate insanientibus; et comitiali quoque morbo oppressis, necessarius est. Sed si acutus morbus est, sicut in cholerâ; si febris est, ut inter horrores, asperioribus medicamentis opus non est; sicut in dejectionibus quoque suprà dictum est: satisque est, ea vomitus causâ sumi, quae sanis quoque sumenda esse proposui. At ubi longi valentesque morbi febre sunt, ut comitialis, ut insania, veratro quoque albo utendum est. Id neque hieme neque æstate recte datur; optime, vere; tolerabiliter, autumno. Quisquis daturus erit, id agere ante debet, ut accepturi corpus humidius sit. Illud scire oportet, omne ejusmodi medicamentum, quod potui datur, non semper ægris prodesse, semper sanis nocere.—*Celsus*, lib. ii. cap. xiii.

SURGERY.—*Examiners*, Mr. Bacot and Sir Stephen Hammick.—1. How would you dress, place in position, and subsequently treat, an extensively incised wound of the Integuments and Muscles, on the anterior middle third of the Thigh? How does such treatment differ from that you would pursue in a lacerated, in a contused, and in a deep-punctured bayonet-wound of the same part? Give your reasons for your management of each respectively.—2. What are the symptoms and appearances in an acute inflammation of the Integuments of the lower extremity which would induce you to think that it would either terminate in resolution, in suppuration, in ulceration, or in mortification? State the foundation for such opinion.—3. Describe the various dislocations of the Elbow-joint, how they are detected, the appearances of the limb, and the mode of reduction.—4. In an Amputation of the Leg, supposing you had the choice of the whole space between the knee and ankle-joints whereabouts would you begin your incision? Give your reasons for such preference; then detail the instruments and dressing you are likely to require, describing every step of your operation; the position of yourself and patient whether it be a right or a left limb; the stoppage of the circulation, whether by tourniquet or otherwise; the incisions; the mode of using a retractor; the sawing of the bones; the securing the arteries, whether by tenaculum or forceps; or if you should require the needle, how it is to be used, the restraining bloody oozing from the cut surface in debilitated constitutions; the dressing of the stump; position in bed; time of renewal of the dressings; the removal of ligatures; and subsequent management of the patient.

PHYSIOLOGY.—*Examiner*, Professor T. Rymer Jones.—1. Describe the mechanical, chemical, and vital properties of Muscular Fibre.—2. What are the propelling agents employed in effecting the Circulation of the Blood during its passage through the venous system?—3. Describe the circulatory and respiratory organs of a Crustacean (*e. g. Lobster*), and of an Insect; and point out the principal differences between them.—4. Describe the structure of the stomach of a Ruminant Quadruped and the process of Rumination.—5. Describe the minute structure of the Liver of a Mammiferous animal, and the nature of the Biliary Secretion.—6. Describe the structure of the compound eye of an Insect.

FORENSIC MEDICINE.—*Examiners*, Prof. Daniel, Dr. Pereira, and Dr. Rigby.—1. What are the advantages of Marsh's process for the detection of Arsenic? and what are the sources of error to be guarded against?—2. How would you proceed to test for Corrosive Sublimate in the contents of a stomach, in a case of suspected poisoning?—3. What are the symptoms and most appropriate treatment of poisoning by Oxalic Acid? What is the average period of death after the ingestion of large doses of this poison? Describe the post-mortem appearances, and state how you would detect the presence of the poison in the contents of the stomach, after the appropriate antidote had been administered.—4. What are the symptoms and appropriate treatment of poisoning by Aconitum Napellus?—5. In the unimpregnated and in the pregnant state, what are the proofs of pregnancy having previously existed?—6. What are the appearances which indicate recent delivery, as shown during life and after death?

MIDWIFERY.—*Examiner*, Dr. Rigby.—1. Enumerate the changes in the female breast which are produced by pregnancy.—2. Enumerate the different varieties of extra-uterine pregnancy; their duration and probable mode of termination.—3. At what period of pregnancy is premature expulsion of the fœtus least dangerous, and at what period is it more so? Explain the reason why.—4. Enumerate the injurious effects which may result from hurrying the expulsion of the child.—5. Enumerate the indications for applying the forceps and for turning.—6. Define the operation of artificial premature labour, and describe the mode of inducing it as recommended by modern authors.—7. What are the injurious effects as regards the mother and child in allowing difficult labour, from contracted pelvis, to go on too long without assistance?—8. What is the diagnosis between prolapsus and polypus uteri?

MEDICINE.—*Examiners*, Dr. Billing and Dr. Tweedie.—1. Describe the symptoms, anatomical characters, and treatment of acute hydrocephalus.—2. Enumerate the principal varieties observed in the expectoration in pulmonary diseases, and the diagnostic inferences to be drawn from each.—3. Detail the principles of treatment in infantile convulsions.—4. State the characteristic appearances and varieties of Rupia. 5. Explain how Pneumo-thorax may arise. Give its physical signs. How is it to be treated?—6. Describe the symptoms and morbid appearances in dysentery. Give an outline of the treatment.

EXTRACTS FROM FOREIGN JOURNALS.

(Translated [illegible] Paris for the 'Medical Times.')

FRENCH.—*Phrenology Examined.* By M. FLOURENS.—Hitherto phrenology has not been honoured by a regular refutation, emanating from the first authorities. The most celebrated physiologists and anatomists of the present period, have been more inclined to treat this subject with contempt, than to oppose it by argument. They have either altogether neglected it, or with Muller have merely deigned a few passing sentences of condemnation. This repugnance towards committing oneself on phrenology is easily conceivable. For the

last quarter of a century this pretended science has assumed all the forms of charlatanism, and hence men of a really scientific character have been unwilling to lose their time in combatting a chimera, or to compromise their name by entering the arena with adversaries such as usually present themselves in this field. When phrenology was advocated by such men as Gall and Spurzheim, it was enabled to obtain some attention, for, to the merit of a kind invention, these anatomists joined learning and talents of a high order. It is even probable that the two chiefs of this doctrine would have assumed a better position in the scientific world, had they not sought so much the favours of the multitude, and regarded more the quantity than the quality of their partisans. But when, after the disappearance of the masters of phrenology, this subject descended into the hands of the vulgar, and was made the theme of a set of ignorant declaimers, its abandonment by men of science became inevitable. An event has, however, occurred of late years in France, which has helped to raise this system from the low position into which it had sunk, and to give to it a certain degree of its former celebrity; I mean the conversion of Broussais to phrenology. Broussais had formerly been somewhat roughly handled by Gall, on occasion of his "*Traité de la Physiologie Appliquée à la Pathologie*," in which he professed a psychological theory analogous to that of Cabanis, and expressed himself with great disdain upon the ideas of the German doctor. Broussais for some years remained faithful to these doctrines, and opposed to the views of Gall. In his work "*De l'Irritation et de la Folie*," published in 1820, phrenology is directly attacked, and formally refuted, by proofs drawn from psychology, anatomy, and pathology. The objections therein contained appeared to him so invincible, that he declared *they could never be answered*; and yet in a few years from that date, Broussais became a fierce disciple of Gall, publicly teaching phrenology, and declared the chief advocate of the sect. This change in opinions has hitherto remained unexplained, but whatever its cause, it was a true triumph to phrenology. The noise created by Broussais' conversion directed attention afresh to the doctrines of Gall, and reanimated their discussion; but, Broussais excepted, no converts of any note were made. It had, however, the fortune to draw towards it, for the first time, an adversary of high standing in the scientific world.

There are few men in France so competent as M. Fleurens to give an opinion on the doctrines of Gall. Devoted for years to the study of the anatomy and physiology of the nervous system, he has been distinguished by the most able and original views on this subject. Endowed with a philosophical spirit, and familiarized with the workings of the human understanding, he has been enabled to expose the contradictions and the errors of the metaphysical part of the system. M. Fleurens examines successively the doctrines of phrenology as laid down by Gall, by Spurzheim, and by Broussais. Attaching himself principally to Gall, as the founder of the system, he shows that his fundamental proposition, namely, that the brain is the organ, or organic seat of intelligence, has in it nothing new, although Gall pretended to give this assertion as a discovery. With a few insignificant exceptions, all ancient and modern physiologists and physicians have expressly acknowledged the special relation of the brain with the intellectual and moral manifestations. It is in the brain that all have placed *the seat of the soul*. The functions of the brain, taken in a general sense, were perfectly well known before the time of Gall. With regard to the second proposition of Gall, viz., that each individual faculty of intelligence possesses in the brain an especial organ, although always suspected and admitted *à priori*, by reason of analogy, still the fact of the plurality of organic conditions being conformable to the plurality of functions, had never been demonstrated. Gall then possesses the merit of having more clearly defined this question, and of having undertaken direct researches for the verification of this idea. M. Fleurens, however, observes, that phrenologists commit a capital error in attributing to the entire mass of the brain a participation in the production of the intellectual and moral phenomena. We must, in fact, abstract from this order of functions at least three parts, the use of which has been directly demonstrated by his own experiments, as well as by those of other physiologists, viz., 1st, the *cerebellum*, which governs the movements of locomotion; 2d, the *tubercula quadrigemina*, the seat of the internal principle of the sense of sight; 3d, the *medulla oblongata*, the seat of the principle directing the respiratory movements. There then remains for the special acts of the mind, and of sentiment, but the brain properly so called, that is to say the hemispheres. But by confining the research of the individual functions of the mind to the hemispheres alone, Gall is equally proved to be in error. Direct observation proves, in fact, that portions of the brain may be removed from all points of its surface, without sensibly affecting the manifestation of intellectual life; and that when this loss of substance exceeds in depth certain limits, sensation, volition, and intelligence, become gradually weakened, and eventually cease altogether. There are not then distinct seats for the various operations comprised under the generic term intelligence, and the seat of these operations appears to be *unique*, as intelligence itself is *unique*.

M. Fleurens then combats with great force, that strange psychological doctrine of Gall, in which he asserts that the acts of judgment, of perception, of imagination, of memory, of reasoning, which essentially constitute intelligence, are but secondary functions, simple accidental modifications of other faculties, and transforms each of these pretended fundamental faculties into so many distinct *individual* and separate intelligences. M. Fleurens dwells particularly on the puerility of that philosophy which attempts to explain each diversity of talent, of instinct, or of taste, by the intervention of a special faculty, designed especially for this purpose. The whole philosophy of Gall, he concludes, consists in creating *multiplicity*, in the place of *unity*; dividing the intelligence, which is one and general, into twenty-seven petty and individual intelligences, and breaking up the brain into twenty-seven small brains; thus substituting an unintelligible chaos in place of the mutual relation and admirable order of the human understanding.

We pass by the remarks of M. Fleurens as to the practical consequences of a system which, according to him, destroys free will, and with free will all essential notions of morality, and come to the anatomical part of the subject. According to phrenology, the faculties are organs; there are as many organs as faculties, for the faculties are merely the functions of the organs: But do these organs exist? Gall never succeeded in showing them, nor even in theoretically defining them. He himself acknowledges that the study of the structure of the brain had taught him nothing, and that it could teach nothing as to the nature, or even the existence of these organs. Anatomy then furnishing no evidence, Gall had recourse, for the purpose of determining the position of his cerebral organs, to the empirical examination of the cranium, that is to say, to craniology, and lays down the following suppositions:—1st, that the organs are situated upon the outer surface of the brain, an hypothesis based only upon the exigences of his system; 2d, that the cranium represents the configuration and prominences of the brain with fidelity and precision, a fact which the least anatomical knowledge proves to be false; 3d, that the functional action of these pretended organs is rigorously proportioned in intensity and energy to their relative size. And it is upon such conjectures that phrenology pretends to have demonstrated the existence of 27 or 35 organs, as distinct in situation, in form, in size, and in functions, as the five organs of the senses!

M. Fleurens then points out the difference between the doctrines advocated by Spurzheim and those of Gall. He shews the contradictions of the two systems of the master and the disciple, and that however they may appear to agree upon general outlines, they are so opposed in their manner of defining faculties, of explaining their mode of action, and even their number, that if the theory of the one be true, that of the other must be equally false. But while strongly condemning the organologic system of Gall, M. Fleurens does not fail to acknowledge the services which it has rendered to the anatomical study of the nervous system, and of the brain in particular, and pays a just tribute to the talent and ingenuity of this celebrated man.

TO CORRESPONDENTS.

The Sydenham Publishing Society.—*Several, Correspondents speak highly of such a Society, and offer to become members, in the event of its being founded, when they will at once give their names. One suggests the difficulty of managing it by an unpaid Committee, and instances the failure of the British Medical Association as a proof. (We should think it somewhat more difficult to manage to keep it up by a* paid *Committee.) A third speaks of the ruin it would inflict on many respectable publishers, and urges us to take no part on either side. Mr. Burns of Edinburgh, doubts whether a London management would please all; and Mr. "H. Hudson Rugg, Surgeon, London," announces that he has a body (no names are given) already established for the purpose.*

An Apprentice.—*Undoubtedly, in reference to the Hall. There might be some difficulty in respect to the College.*

Capt De Borgh.—*We have not given the part enquired about. The whole work in German may be got through Mr. Black, of Wellington Street, North.*

Clarke's Apparatus for Fractures of the Lower Extremities.—*We have been requested to call attention to this* ingenious and comprehensive *improvement, but it was so well described in a past number of our journal, as, we fain hope, to make further notice unnecessary.*

A Subscriber *forwards an advice bill placed in his hand, containing the offer of advice and medicine for sixpence each application, by Mr. Joseph Nelson, M.R.C.S.L., at Mr. Dunn's, the Chemist's shop. We can only hang out his name with* "hunc tu caveto." *The College should risk (if there be risk in the matter) the expulsion of such fellows.*

Periscope, Junior, *has our best thanks.*

M. R. C. S. I.—Mr. H. P.—Argus—Why and Because—Emptor—Four or Five Constant Readers—*no space.*

We shall think over Mr. Dawton's paper.

Mr. Prideaux's note was received. We receive subscriptions at all seasons.

XX—Minor—Punch—A Medical Reformer—"A Wise Son"—"A Provincial that was," *have our thanks. We shall sacrifice the latter's wit (if compelled by that demon,* space*) with much unwillingness.*

B. M. T. *will find his answers in our leading observations, as Milo will find his in our advertisement page.*

The Conclusion of Orfila—Lectures by Serres (continued) on the Development of Organs—and Dr. C. I. B. Williams in our next.

N. Y. *It was resisted as an unjust demand, and with some success, since it was reduced nearly one half.*

NOTICE.

ON THE 1st OF DECEMBER NEXT, WILL BE PUBLISHED, AS AN APPENDIX TO OUR ORDINARY NUMBER, A **MEDICAL ALMANAC**, REPLETE WITH MATTER THE MOST VALUABLE AND INTERESTING FOR THE MEDICAL PROFESSION.—IT WILL CONSIST OF 72 QUARTO COLUMS. PRICE 1*d.* PLAIN, 5*d.* STAMPED.

THE MEDICAL TIMES.

SATURDAY, NOVEMBER 12, 1842.

Pares cum paribus *difficillime* congregantur.

The British Medical Association held its annual meeting at the British Coffee-house, Cockspur-street, on Tuesday evening. The meeting was composed of between one hundred and one hundred and twenty persons, and the refreshments which followed were partaken of by about sixty guests. Instead of making the proceedings the subject of an extended report, we shall present them in the condensed form more suited to their absolute importance, and make concurrently such remarks as their nature and bearings may suggest.

The chairman, Dr. Webster, of Dulwich, opened the meeting with some general observations. He seemed to have two objects in view—first, to prove that the Association was neither contemptible in its constitution, nor insignificant in its doings; and, secondly, that in the present state of the profession, and in the prospects held out to it by Sir James Graham's bill, there was a necessity for the medical body's doing something extraordinary. The preparation of a proposed Act of Parliament—deputations to Lord Campbell—Sir J. Graham—and the Poor-Law Commissioners—were the evidence mainly adduced to prove the successful working of the Association, to whose exertions the speaker mainly attributed the merit of those Poor-Law ameliorations, which have commonly been supposed to belong to the independent medical press—the general expression of medical men's opinion—and to the active personal exertions of the late President of the College of Surgeons, who certainly, in this matter, has not yet received his due from the medical public. Dr. Webster re-announced the heads of Sir James Graham's bill, which differ in such inconsiderable trifles from the statement we have already given of the measure—that we think it unnecessary to reproduce the details. The report prepared by Dr. Webster was then read: it contained an exaggerated statement of what the Society had done during the last year—expressed elevated notions on the Association's power of volition, which was declared equivalent to any other body's action—and referred the subscribers for a statement of their accounts to some future day,—some unnamed accident preventing any being forthcoming at the members' annual meeting.

Professor Grant, in a speech that occupied about two minutes, dwelt strongly on the paltry subterfuge Sir James Graham's bill involved—inveighed against his neglect of the Irish and Scottish medical corporations,—and insisted, in despairing accents, on the necessity of some grand organization. Dr. Grant seemed anxious to have the corporations as quickly as possible in the class of extinct remains, and evidently felt that the circumstances about him gave him little grounds for hoping so capital a subject for the exercise of his brilliant powers of classification.

Dr. Marshall Hall enlarged on the high qualifications and endowments of medical practitioners, and compared these with the position they occupied as aliens in the two Colleges, or the third licensing body—the Company. He had himself been an alien in the College of Physicians for fifteen years—and his answer to a physician, who asked him what he could grumble about now, being a Fellow? was—that "he had the recollection of fifteen years' exile, in his own land as it were, to grumble at." He referred to the numbers—the intelligence—of general practitioners, and reminding them that in both was *power*, urged them to use it. Their place was to *demand*, not to petition. He also recommended unity and organization—spoke of the delights of fraternization, and more intimate intercourse, assuring his audience, that they would be truly happy,

—si bona sua norint.

He proposed that, with or without law, the profession should form itself into one Faculty—and deprecated strongly the maintenance of such degrading terms as apothecary and general practitioner, wishing both to merge in that of Member of the Faculty. He finally, on the plea of ill-health, announced his approaching adieu to medico-political life, asseverating his changeless opinions. The president, announcing that he had no seconder named for the resolution, suggested the duty to Mr. Pilcher, who briefly remarked that medical men, from their superior attainments, might be safely entrusted with discretionary political powers, which might be dangerous in other hands—and suggested this as a reason why the government of the profession should be in its own hands. It would seek not its own aggrandizement, but the public good. Dr. Lynch followed in an eloquent and much-admired speech—expressing his wonder that medical corporations should be now the only existing self-elective anomalies in British Government—and citing the opinions of Aston Key, Professor Kidd, and Sir James Clark on the utter incompetency of the two Colleges to discharge their duties decently to their members' profit or satisfaction: he descanted on the political apostacy of Lawrence—inveighed against the preposterous arguments adduced in favour of the present corporations—and especially against the segregation of one class of practitioners for the poor, and another for the rich,—the division of labour, &c., and affirmed that the curricula were lengthened or shortened as the College finances needed. He pursued in detail the various grievances of the profession, and expressing a high opinion of the general practitioner, whose skill he placed above that of either the pure surgeon or physician, expressed a hope that that hard-worked body to which he belonged would one day get their real merits, and occupy that position to which their education and services to humanity gave them a fair title. He concluded by a strong reprobation of the proposed new bill, which, it was declared, would make bad worse. Here, the president read a letter, which he described as a blast from the north, which expressed warm approval on the part of a Medical Reform Society of Glasgow, of the scheme of starting a new Faculty by the members themselves. Mr. Riadore Evans, who was startled by an appeal to him to support a resolution which had evidently not been communicated to him, now shortly expressed his hope that something would be done—with his conviction that the project proposed had its difficulties.

After Professor Kidd and Sir James Clark had been enrolled honorary members, and two other gentlemen elected ordinary members, Mr. Grainger was called on for his oration on Medical Reform. The essay was perspicuously and well written, abounded in an article we should not have expected to find near so many *tetes exaltees*, sterling common sense,—and, on the question of Medical Education, advanced opinions deserving the highest consideration. It will shortly appear in print, when we shall renew our acquaintance with it, not, we believe, without pleasure and advantage to our readers.

After an unostentatious supper, in which—according to the report before us—the two great political qualifications of the ruling duumviri,—the overflowing graciousness of the president, and exuberant appetite of the polite secretary—were favourably exemplified, a series of toasts were given, and the festive scene became enlivened with a merriment which, honourable or not to the cause, must have been a source of much happiness to those assembled and elevated to the fit humour for appreciating it. If we may believe the report, a gentleman's song of love, with an overhanging large picture, called, by a speaker, "*luscious*," of a nude Venus in the arms of Mars, formed, with their connection with the reflex functions of the unexcited Dr. Hall, an exhaustless fund of oratory, and endless source of amusement.

The following, apart from the routine votes, were the Resolutions: we especially invite attention to that we give last:—

That while we rejoice that the persevering efforts of the profession have obtained from the Poor Law Commissioners the ameliorations contained in their late Medical order; the association will continue their best endeavours during the next Session of Parliament to procure further amendments in the present defective system of medical relief.—That the plan proposed to the Commissioners by this Association

for the poor under certain regulations, to select their own medical attendants from the qualified practitioners in their neighbourhood, would be alike beneficial to the poor, and satisfactory to the profession.

That any measure of medical reform, which does not contemplate the union of the Profession into a representative body; equal rights and privileges as members of that body: uniform qualifications for a title to practise throughout the British dominions; and protection to the community and the profession from illegal and unqualified practitioners, will be most satisfactory to the profession, and will be strenuously opposed by the Association.

That it would be highly desirable, under existing circumstances, to unite the Medical Profession into one Representative Body or Faculty:

That a standing Committee in London, should be appointed by the various Associations, and by County Committees to promote this and other important objects; to watch proceedings in Parliament, and to act as circumstances may require.

That a Committee be appointed by the Council to acton behalf of the Association to correspond with other Associations and Committees, for the purpose of forming the Central Committee.

The object of this Resolution appears to have been, to sound the medical public on the possibility of forming a Faculty of Medicine, whether Parliament or Law sanctioned it or not. If the sanguine concocters of the scheme had any notion of its feasibility, *through their agency*, before Tuesday last, the chilling reception the amendment met from the gentlemen assembled, must have dispelled the delusion. The truth is—and we express the repulsive truth with the sincerest regret—there is nothing (at present) in the Association calculated to lead to the remotest chance of its proving of usefulness. There is utter disorganization in its management: there is in it no brotherhood of sentiment—no kindliness of feeling—no bond of mutual regard or esteem—no harmony of design—no concert of action—no element, in short, of unity or cohesion. The Council considered as a body of gentlemen meeting, considering, discussing, acting,---as anything, in truth, but a prospectus list of names, is a MERE SHAM. Mr. Grainger is an annual shew-card; Drs. Grant and Hall announce their retirement; Mr. Farr is silent; Dr. Granville away; speakers cannot be found numerous as Resolutions---yet this crippled, disorganized thing, this worst-constituted and worst-managed Society in the Empire, broaches a scheme which, with the best circumstances, and under the wisest direction, would present all but insuperable difficulty of realization. To do the Association justice, there is real magnificence about *its pretensions*---it is the wren with the eagle's cleaving wings, and it never moves into absurdity without being carried by native weight to the culminating point.

We deplore---we deeply deplore---to augur so little succour from this quarter, at a time when all the forces of medical reformers should be in requisition, and shewing their best metal, under the best guidance. But the crisis is imminent, and there should be no misunderstanding: we should exactly know what we have to count on. It will be no consolation, after the supposed support has sunk under us, to say we had hoped better things. The REED IS ROTTEN,---let it be known. Will the profession rely on it---or on *themselves?* If on it---we are in the hands of the Philistines, and the Corporations have us for another century. No power on earth can save us! If on ourselves---boldly, prudently, energetically --- we may yet shew the enemy bold --- aye, *successful* fight. But there is no time to be lost.

The letter of Mr. Guthrie published in the MEDICAL TIMES, a fortnight since, has produced a *small* sensation. The country practitioners, are in various degrees of excitement; the council of the College of Surgeons are by the ears—and each day brings with it, a thousand intimations of the circulation of our Journal, in the shape of applications to the College, of Gentlemen, who wish to be examined "on their merits practically."

The Councillors are, to use an Americanism, clearly in a very tarnation sort of pickle, and how they will get out of it with respectability, is a question of some interesting speculation. Deny the practitioners the boon the late president so providently extended to them—they dare not. The word of Mr. Guthrie has been given---the emergency demanded it—and he is not the sort of man to recall it. The council then must eject the ex-president—and mortally offend and disappoint and inconvenience numbers of country practitioners—or these must be inducted into the College on satisfactory proof of their competency supported by the usual fee. But *can* the College—*dare* it insist on the fee under such circumstances? Through their ex-president, they have so operated on the Poor Law Commissioners, that these now insist on the London College's diploma: did they do this for their own emolument, or the public good? Who will be in doubt, if they make the arrangement so procured, a source of corporate and individual lucre? They must then admit the experienced practitioner, and they dare not in decency, derive from the admission, a petty pecuniary profit, which would disgrace them as trafficking negotiators and mercenary tradesmen for ever.

PROFESSOR OWEN, F.R.S.

THE medical profession must rejoice to learn that the Royal favour, which has been confined heretofore to the eminent cultivators of the exact sciences, as Herschell, Airey, Faraday, has this year been extended to Professor Owen, whose invaluable services to Physiology and Comparative Anatomy have long been acknowledged by the Institute of France, and other learned Academies of Europe. We shall, at present, limit ourselves to alluding to his Catalogue of the Hunterian Collection, the different volumes of which must have been in the hands of many of our readers. The Council of the College have informed us, in the preface, "that they have great gratification in acknowledging the unremitting labour which has been for many years bestowed on this great work by Mr. Owen, one of the Conservators, and now Hunterian Professor of Comparative Anatomy and Physiology, to the College, to whom its publication has been exclusively confided." The Hunterian Collection cost £30,000 of the public money, when it was without a Catalogue, and so continued for many years, a sealed book to the student. By how much is its value increased now, that, by its scientific arrangement and description, "he that runs may read it?" We do not remember any scientific services to the State, for which a pension of £300 has been awarded, of a more solid description, or better merited, than those which Mr. Owen has devoted, during the best years of his life, to this important work. We congratulate the distinguished Professor---we congratulate, still more, the Government --- on this most judicious act of justice.

PENCILLINGS OF LIVING MEDICAL MEN.

DR. HAMILTON ROE—MR. LYNN—DR. BURNE—MR. HALE THOMPSON,

Dr. Hamilton Roe, whose magical influence over his congregation, we attempted to describe in our last sketch, takes the means to command success. The style of his oratory is well adapted to excite tender emotions. It is Moore without his metre—poetry converted into prose, and without its measured chains. His lax terms, his voluptuous, his oriental imagery, is entrancing. You feel that the loves of the angels, if not *fact*, are at least more than *fiction*. His sparkling fancy lays the whole range of creation subsidiary to its invasion, and it has ample scope for its excursions upon the vague immensity of the endless sea of theology. He invests ordinary subjects and otherwise uninteresting, with a charm that makes his devotees feel that his doctrines are full of pleasing reveries, and the warm imaginings of the young and blooming lady of high and hot blood can, under his guidance, venture into the sacred bowers of even Eastern poetry without peril.

This glowing and impassioned language bears all the character and glory of spontaneous enunciation, or rather of inspiration. But these unprepared creations of religious rhapsody are carefully and artfully digested in the study, and afterwards thrown off with such volubility and earnestness as to impart the illusion of extemporaneous oratory, and its enthusiasm and sincerity are calculated to make converts. Ars celare artem, is the highest proof of rhetorical proficiency; he certainly gives it the appearance of natural and momentary impulse. The purple patches of embroidered *eloquence*, he works most skilfully into the frame-work of his discourse. It requires a very discerning ear to detect the real from the mock mosaic. A very prepossessing appearance, graceful animated action,—

> Hands, lips, and eyes, are put to school,
> And each instructed feature has its rule,—

exercise their wonted power over a very susceptible auditory, to whom it would be sacrilege—nay, almost blasphemy, to insinuate that his addresses were drawn from artificial sources of emotion; and not from the deep and troubled fountains of the heart. We

ought to say a word upon the composition of his obedient and fleecy flock. They are of the order miscellaneous. The gentler sex preponderates considerably; to the majority, the air *di tinque* applies. They look very grave, but their vanity, though of the serious character, is displayed in their dress, and equipage. The elder portion of this class, are known by their conspicuous *piety* and *paint*, and by the elaborate and ostentatious humility with which they glide into their seats. A pleasing difference to this group of devotees, is presented by the gay, the graceful, the scented, the sweet-spirited, the cherub-lipped lispers of the unknown tongues, whose Heloise tenderness, and impassioned innocence, make you waver whether you will embrace them as sisters in spirit or—not. Their eyes, as they are lifted up in adoration, are at intervals tenderly and surreptitiously directed to their companions of the opposite sex, who are overjoyed if the fond one in the pious up-turnings of her eye during the excess of a fit of devotion should abstract her mind one moment from heaven to think of him. This mixture of human with evangelical affections is very edifying; it is a beautiful specimen of the doctrine of sympathetic attraction, or rather of single and elective affinities; an illustration of the, at times equally suspensive magnetism of earth and heaven.

There is another class some ten years older, who oscillate in a state of disagreeable suspense between these two extremes, and who finding themselves neglected by the latter, are disposed to dedicate themselves to the former, and who flock to the doctor to teach them resignation and self-denial.

There is another class—they reckon very few in numbers, but are distinguished by their obstreperous zeal. Those who have reformed—who have turned from their evil ways—who have occasioned much joy in heaven—who now piously incline to give up the plural for the singular number. Now, their passions decline, and piety makes inroads upon their boundaries.

Servants, too, are to be met with here of noble families—who are equally solicitous of their temporal, as well as spiritual, welfare, and who on a principle of reciprocity, consider that the maid should be of the same religious opinion as her mistress. This class forms a corps of peripatetic advertisers of the doctor's skill and goodness.

We cannot enter farther into an analysis of all those males and females who assist at this fanatical mummery. The doctor, as high priest or grand referendary, is consulted upon all essential points, something upon the principle of a chamber lawyer; his opinion is a decree final and infallible. He does not meddle in matrimonial matters, as has been alleged.—There is a committee of persons whom we call of the neuter gender, to whom these delicate negociations are intrusted.

His evangelical is blended with his professional reputation. He is followed by poor and rich. His hall down in Hanover Square is surrounded every morning, and we should judge that his practice is extensive and aristocratic. He has written, but done nothing for science. He walks round the wards like a priest in a processsion, with the aspect of abstract and mystical meditation. Another day with leaden eye he seeks the ground, and seems industriously employed in counting with exact precision the nails in every board of the ward which he is traversing. His work on diseases of children evidences a total ignorance of composition. He ventured some time ago to send a case of cholera to the Lancet. It was a very poor affair. It would shame the penmanship of the humblest general practitioner, whose writings often far surpass the literary productions of our presuming physicians. In this article he advanced no scientific explanation of the phenomena of the disease, only "that when a violent spasm came on, the patient writhed about the bed, and that he recommended empirically laudanum and ammonia." He shews zeal and ability in his official duties, and when not wrapped up in his musings, is jocular and communicative of what he knows. As a lecturer he is neither eloquent nor fluent.—The principles of his therapeutics are not fixed—his practice is equally variable. He looks for the *causes* of disease in organic lesion. He is a solidist; he might as well search for wisdom in a wig. He is a kind-hearted, amiable man, always ready to do a good action, and never unwilling to befriend those who are not in a condition to help themselves. The lines of the poet may, without inappropriateness, be quoted for him,—

> Thus to relieve the wretched was his pride,
> And even his failings leaned to virtue's side;
> He tried each art, reproved each dull delay,
> Allured to brighter worlds and led the way.

Mr. Lynn is nephew to the late senior surgeon, and forms one in the many instances in our charitable institutions, of the effects of nepotism—not but what one less fitted than he might have been elected yet it is certain, a less near connexion to a preceding *pure*, would have been a disqualification to Mr. Lynn, as he is no favourite with the governors and medical officers, and the reason is obvious. He is too unassuming, too mild, too gentlemanly a man to be a match for the dictatorial individuals who form the majority of his colleagues and the house committee. By such men he is regarded as a person whose opinion is far below any of the other medical officers. He consequently receives many slights without notice; which none but one aware of having been raised by the fortuitous chance of relationship would submit to. Mr. L. is far from being without talent; he is a dapper active man, with an intelligent countenance, perceptive and reflective organs well marked, on a well developed head. He had been for twelve years a favourite pupil of John Hunter and is, as a matter of course, a good anatomist; he is also a safe operator: imperturbable sang froid, great presence of mind, manly confidence in the conclusions of science and reason, are his distinctions. He has not contributed even the widow's mite to the Westminster poor box of improvement. Factis non verbis, is his motto. He has no ambition to appear in print. They say that he is a man of no literary or scientific attainments. We cannot predicate whether he is so or not. We rather think that it is not true; he abhors the unprofessional parade, and vain-gloriousness of his bombastic colleague. Notoriety, the passport to all monopolies and corporate bodies, he shuns. The echo of his name and fame reverberates not beyond the stuccoed walls of the institution of which he is a diligent and useful officer. He is an hospital surgeon nevertheless and why not a member of the council? He never made them tremble beneath the thunder of his denunciation. Fear and sycophancy are the keys that open their closed doors. He never truckled like the crawling slimy reptiles who, with less merit and pretension, disgrace even the sittings of this secret council. His manners and appearance are unpretending and agreeable. He is bland and obliging to all subordinate to him, and friendly, colloquial, and instructive with the few pupils that still remain to walk the wards. There is no pity or sympathy felt for his rejection by the council of the college. Their cruel, capricious, and unjust treatment of several excellent men, is another of the multitudinous evils which the present abominable system entails. They are now wholly irresponsible They can set the indignation of the profession at defiance. What happened to Lynn yesterday, may occur to another to-morrow. They may pass over whomever they think proper. Every man whose name is on the list of the college, has an interest in resisting their assumption, and should join his brethren in bringing them under the controul of the profession by making them eligible periodically by all the members.

Dr. Burne, aged 40, is a tall, well-looking man, and has the name and credit of being a clever man. He is a very fair and fluent lecturer He married the Bishop of Hereford's daughter, which advantaged his professional prospects. His clinical instruction is worth attending. He published an octavo on typhus. It is a summary of the information then known; he divides it into adynamic and inflammatory The 2d division, or adynamic, includes the putrid of Sydenham, the slow nervous of Huxham, typhus gravior, typhus mitior, and synochus of Cullen, and the essential of Clutterbuck. In his preface he says, if we consider the limited views of some authors, we confess that there is much wanting to perfect our knowledge of this disease. The accuracy of this observation we fully assented to after a perusal of the doctor's production: "Ancient writers," he observes, "had to contend with the disadvantages of a defective acquaintance with morbid anatomy, and, therefore, could not possess the means of attaining correct notions of fever." The merest tyro is aware, that of all the diseases that flesh is heir to, typhus is just the one which pathology throws the least light on. Those who attributed it to lesions of head, such as Clutterbuck, to lesions of chest, of stomach, of liver, of mucous membrane, of intestines, have found out their error; and the profession begins to look from the solids to the altered and varied state of the circulation; for this is the true explanation of the cause of typhus. The sole study of solidism, even pushed to extremes, affords only negative information; animal chemistry is the only channel through which we can hope to find a solution of the difficulty.—The doctor lays down rules which can never be followed and formally describes distinctions which never existed. The book is full of professional proverbs, the paternity of which belongs to, and we fear will die with him. They remind us of Seneca's observation,—

Nil sapientiæ odiosius acumine nimio.

He lays down, too, theories with all the importance of fundamental doctrines. We had reviewed at some length—for, like Johnson, we delight in that intellectual chemistry which can separate the good from the bad qualities in the same individual, and we endeavoured to exercise it with regard to the merits of this work, but our sketch will not allow room for it. The exciting cause is, in his opinion, cold. He very properly rejects the absurdity of localising the seat of fever, and laughs Clutterbuck out of the field. His means of treatment are emetics, aperients, bark, cold affusions, bloodletting, mercury, opium, stimulants—a pretty extensive range of therapeutic agents. Bloodletting, however, he uses with caution, amounting to prohibition. It is now very generally regarded as rank homicide in this disease. The authority, or success, of Dr. Southwood Smith are not able to induce practitioners, who have witnessed its murderous effects, to recur to it. His views and assertions we intended to meet by quotations from the numerical plan of Louis, especially his observations and animadversions upon the ancients, upon the pulse which Louis proves to be correct and the Doctor wrong. It is on the whole the best work we have on ty-

phus, excepting always Stevens and Louis's able works. He has also written an useful work on constipation—his style is more copious than correct.

Mr. HALE THOMPSON is the prince of puppies: we wish, to regard our professional brethren, through an achromatic medium. The annoyance, ignorance, and impudence, of some men will not allow us. A judge said to a lawyer, who expressed his surprise at his tolerating it in a witness; "I was paralyzed," replied he "with admiration; his impudence was sublime." A very opposite feeling is created by witnessing the escapades and endless altercations of this very conceited and empty-headed young man. We never knew a man whom the great body of all those who come in contact with him are more unanimous in disliking. He is a very insignificant personage—there are no salient points about him—there is no intellectual character, or history, to refer to. He is the Count Fathom of Westminster. He got his situation by money; he married a banker's daughter. He is a good-looking, dark, curly-haired gentleman, and keeps a dashing equipage. He was *goosed*, as they term it, out of the chair of Westminster School. He has an Infirmary for Diseases of the Spine at the back of his house. His treatment, and practices to attract rich patients, I wish not to allude to. He is not liked by the pupils: they tell a story of a pupil of the name of Deschamps purposely asking him if the bone of the os coccygis was the last phalanx of the thumb, and that he answered in the affirmative.

We would remind him that there are two orders of intellect to be combined, to be eminently great—perceptive powers which exist in the collection of facts, and the reflective powers which systematize and draw conclusions. Has Hale Thompson ever furnished a fact hitherto unobserved? Has he favoured science with any valuable inductions? Has he in any way fulfilled his high functions, by exposition, scientific elucidation, or accurate practical observation?

We would also urge upon him Swift's proverb,—

"Every man has just as much vanity as he wants understanding."

The hauteur which he assumes—the peacock air—only provoke reflections which had better be avoided. He is a very little personage—his opportunities will never make him otherwise. Train and discipline a dwarf, he will never become a giant. He is a living evidence of the iniquity of our system of Hospital Elections. Mr. Guthrie has, in a recent vindication, called by courtesy a clinique, acknowledged the glaring abuses that exist there. This is the grossest and greatest of any. Thompson, as his fag, will be one day, perhaps, a member of the council!!!

PROBE.

REVIEWS.

On Injuries of the Head Affecting the Brain. By G. J. GUTHRIE, F. R. S, Surgeon to the Westminster Hospital, Opthalmic Hospital, &c. &c. Churchill.

THIS is the title of a work which exhibits in a condensed, and highly interesting manner, the result of much experience, in a very important, but difficult, branch of surgery. The author, who is well-known in the surgical world, and who stands at the head of perhaps the most rising school in London, has had most admirable opportunities of studying the subject both in military and civil life, and from the acknowledged talents and attainments of the author, we had reason to expect a practical work of no ordinary value, and we have not been disappointed. The author is a man evidently of acute observation, and of an energetic, if not profound mind. He dashes at once into his subject, and is practical throughout. Although too heedless of method in the disposition and arrangement of the different parts of his subject, his style is perspicuous and forcible. His cases are so condensed that they might have been indited on the battle field, and the principles he inculcates so succinctly, and comprehensively expressed, that they might have been delivered in consultation in a camp hospital. All is brief—all directly to the point—all excellent. We have in the work before us, a body of practical information on injuries of the head, which will bear comparison with that contained in any work that has been published. It possesses all the fascination, without the prolixity, of the great work of John Bell, and as a guide to practice, is infinitely more to be trusted to than that work. Indeed, we do not know a book, not excepting those of Le Dran, Petit, Dease, Pott, Desault, Bell and Abernethy, in which the treatment inculcated throughout, is more accordant with sound physiology, and approved and successful practice. Our space this week will not admit of a more extended notice, but we shall take an early opportunity of transferring to our columns all the more important novel points of doctrine, or of practice, which the work contains.

Commentaries on Some Doctrines of a Dangerous Tendency in Medicine, and on the General Principles of Safe Practice. By Sir ALEXANDER CRICHTON, M.D., F.R.S. Physician to the Emperor of Russia, &c.

(Concluded from page 96.)

SECOND NOTICE.

Possibly a little of the *laudator temporis acti* may be discovered in this work; but it is pardonable in one whose only aim in writing was the improvement of the profession. But if the sentences we have been quoting are certainly extraordinary, when we find the author detailing at some length in the same and ensuing pages, the treatment of Dr. Millar and Dr. I. Clarke; treatment which both these physicians declared proved successful in their hands, which has been adopted by numerous subsequent practitioners, and which we are able to vouch from our own by no means trifling experience to be, with certain modifications, highly efficacious.

This treatment, or, as Dr. Crichton terms it, innovation,—

consisted in giving from one to two ounces of cinchona in substance, together with a strong decoction of the same in cinnamon water, in the *very first stage of continued fevers, even if the pulse was hard, as well as quick, the heat great, the skin and tongue dry, and the urine scanty. Violent headache did not prevent this practice*—pp. 46-7.

In Dr. Millar's testimony our author is not disposed to rely much, because "he was better known among his contemporaries for the oddity, than for the soundness, of his opinions." This is certainly not a good reason. The "oddity of his opinion" might have arisen from his having been, as he decidedly was, before his age, and being such he paid the penalty of being sneered and talked down. But the same thing happened to Harvey, who lost his practice for daring to publish his theory: to Bruce, for telling us more than we dreamed of Abyssinia, especially of the fountains of the Nile, and of rump steaks from living oxen—to Gall for shewing us that the spinal chord was *not* a prolongation of the brain—to Winsor for offering to illuminate London with gas—to the projectors of "*The Times*" newspaper (for the present principal proprietor, Mr. Walter, bought that tremendous moral engine for a few sacks of coals!) to Elliotson for advocating phrenology, and for introducing Prussic acid, quinine, and creosote, for describing glanders in human subjects, for practising auscultation, and exhibiting mesmeric phenomena—while Crosse was all but annihilated because he published his discovery of the Acarus Galvanicus, since placed beyond the possibility of question, by latter experimentalists; and last, not least, Dr. Stevens, author of that valuable work on "the blood," to which we shall have occasion possibly to refer presently, was all but put out of the pale of the profession for declaring from frequent experiment, that the red colour of the blood was owing to the presence of the salts of the serum. Nay, the late Dr. Edward Turner went so far as to declare, in the last edition but one of his "Chemistry" published during his lifetime, that he had made similar experiments, and that the results were contrary to those given by Dr. Stevens. Yet, in the last edition, revised by himself he was forced to contradict this contradiction, and to acknowledge the truth of what the accurate and ingenious Stevens had before stated! In this instance, Dr. Turner had a theory to uphold—a prejudice to support. A friend of his, Dr. Englehardt (we hope we spell his name correctly) had published a treatise, in which he thought he had established beyond the possibility of cavil, that the blood owed its colour to the presence of an oxide of iron.—The upsetting of a bason of water, on a lady's silk dress by a jealous favourite in the reign of Queen Anne, led to heaven knows how many years' war, and so this hankering friendship, of Turner for Englehardt, led to the denial of what we believe to be one of the most important discoveries of modern days, the cause of the florid (i.e., healthy) condition of the blood.

To resume:—Dr. Crichton however, considers Dr. I. Clarke as a physician and practical man in every way to be depended upon. The doctor says,—

In Dr. I. Clark of Newcastle, we have to deal with a very different personage. He had been regularly educated to* medicine and surgery in the University of Edinburgh. During many years he had served in the navy, and had often seen the typhus gravior (the hospital and camp fever) in a variety of climate. After retiring from the service, he established himself in Newcastle, and was appointed physician to the infirmary and dispensary of that city, in which typhus often raged afterwards as a contagious epidemic; consequently, his opportunities of observing that disease were very great.—(47.)

This is a strong *prima facie* evidence that Dr. Clarke was a man in whom great reliance was to be placed, but when Dr. Crichton informs us that—

His history of symptoms is correct and good, and his precepts for the health of seamen, and the prevention of contagion in the navy, and besieged cities, are judicious and useful.—p. 47.

We do not see how Dr. Clarke's testimony is in any way to be set aside; or that his treatment, which, as we have before said, has been found successful in the hands of other practitioners, is to be considered as any other than that which, under certain limitations, all judicious medical men should adopt. We have had an opportunity of seeing both the treatment of Dr. Crichton and that of Dr Clarke tried very extensively in the Tropics, and both successfully. That Dr. Crichton's is more in accordance with the general view of the profession, we readily concede, but we observed

* Was Dr. Millar not a regularly bred man also?

that patients healed according to Dr. Clarke's plan, (with certain modifications, which we shall give immediately) recovered much more speedily than by Dr. Crichton's. It may be, therefore, useful to state in what manner these fevers were treated in the West Indies. In nearly every case we bled. The blood was then tested according to the invaluable recommendation of Dr. Stevens. A small quantity of common salt was thrown in the basin, and if, as it generally was, it was very dark, immediately that the salt came in contact with it, it assumed a crimson hue, clearly indicating the cause of the dark or black colour to be a deficiency in the salts of its serum. If, on the other hand, the blood was not remarkably dark, we by no means regretted having let blood—since the patient could evidently bear venesection. But in no case, whatever might be the symptoms, was venesection repeated in our practice. We have seen it repeated in the practice of others, and always with decidedly bad consequences. Resinous purgatives, combined with sulphate of potash, soda, or magnesia, or the phosphates and carbonates of the same bases, enemata if indicated; sometimes, but very rarely, mercurial purges were resorted to, but mercury was never exhibited with any other intent than to purge—and that we may dismiss whatever we have to say of this most dreadful poison when injudiciously administered, we add, that we never perceived any good effects from it after the first dose, but quite the contrary. On the first remission of fever, which generally took place during the action of the purgative, though this remission was not always well-marked, quinine was given, sometimes in wine, sometimes in water, at others, with the sulphate of magnesia or soda. For common drinks, effervescent draughts, tamarind or cocoa-nut water, or even very weak wine and water, but this latter was of very questionable utility. If great heat of skin, thirst, parched tongue, and anxiety, were present, spunging the body with cold water, ventilation, and nitrate of potass in ten grain doses every hour, were put in requisition. This treatment being persevered in for six or seven days, the fever generally declined on the eighth or ninth day, and on the tenth the patient was convalescent. This treatment was first generally made known by Dr. Stevens, though Mr. Cameron (*Treatise on Diet*) claims the merit of having first put it in practice, and accuses Dr. Stevens of having borrowed from him the idea of treating typhus, cholera, and the endemical fevers of the West Indies, with saline medicines. Dr. Ryan correctly remarks that, "nitrate of potass was given in barley-water, whey, and other diluents, and in powder combined with antimonials, in febrile and inflammatory diseases, long before either discoverer was in existence." (*Formulary of Hospitals.*)—But this must not be allowed to detract from the great merits of Dr. Stevens, or even Mr. Cameron. To Dr. Stevens must be conceded the honor of having first shewn the *rationale* of the saline treatment. It is also remarkable that, while the writer of this article was pursuing the same investigation as Dr. Stevens, and had adopted, with slight modifications, a similar treatment, Dr. Wilson, of the Middlesex Hospital, was led to much the same conclusion, and pursued very nearly the same plan. Here, then, are three physicians, each unacquainted with the investigations of the other, yet all agreeing much about the same time in their treatment—each believing himself the discoverer of a new system. We, therefore, readily concede the honor to Dr. Stevens; not only because he published upon the subject (as did the writer of this article), but because he shewed the *modus operandi* of saline medicines, and, we may almost venture to say, discovered the cause of fever.

This is Dr. I. Clarke's treatment:—

I have shewn the safety and advantage of exhibiting bark early in confined fever, which occurred in my practice in this kingdom. From 1770 to 1791, I have attended about thirteen hundred patients in all the varieties of continued fever, and I do not remember that above four cases have come under my care, where the medicine failed."—*Observations on Fever.*—p 790.

Dr. Crichton adds—

"This is nearly the same kind of confident language, which Rasori, Dr. Armstrong, and others employed, when they recommended forty ounces of blood to be taken away at once, and repeated in the very same kind of fever."—p. 17-8.

Here, we must admit, the "folly of dogmatism" is painfully conspicuous. To lay down rules for the *quantity* of blood to be taken from a patient, is a blunder too obvious to be exposed. The practice of Rasori and Armstrong did more harm, perhaps, than any other, not excepting the Brownonian theory, and was soon abandoned; indeed, Rasori had the courage to abandon and condemn his own treatment, after pursuing it unsuccessfully for many years!—He substituted *counter-irritation*, on the ashes of which Dr. Granville erected his superstructure. The practice of Dr. Clarke of giving laudanum in large doses, at the commencement of fever, we hesitate not to condemn, with Dr, Crichton, "as bad and hazardous treatment." p. 19.—But that Dr. I. Clarke's treatment, taken as a system, was judicious and scientific, we entertain not a doubt. Here is what Dr. Crichton himself says:—

I ought to have observed that the preceding statement of Dr. Clarke relates particularly to the treatment of contagious typhus, or hospital fever, in which disease it has been proved incontestibly of late, that local inflammations are generally detected after death. Nevertheless, in all the stages of this fever, Dr. Clarke gave two ounces of strong infusion of cinchona in boiling cinnamon water, every half hour; or an infusion of the same strength, i. e. an ounce of the cortex to ten or twelve ounces of fluid, to which he added occasionally conserve of roses, one ounce; diluted sulphuric acid one drachm; and one ounce of French brandy: and to such mixtures he also added the powder of bark, as soon as he conjectured the patient's stomach could bear it. In the advanced stages he gave in addition, the Virginian snake root and ammonia. I well remember that the publication of Dr. Clarke's work produced a great sensation among the London practitioners of medicine. Most of us had been pupils of Cullen, and had imbibed his doctrines, and imitated his practice. Few could be induced to try it at first. The mild diaphoretic and antiphlogistic plan was undeviatingly pursued by the greater number, for the best of all reasons, because it was found generally to be safe as well as successful. Nevertheless, some physicians of reputation and experience began to make cautious trials with the tonic plan, and their reports were undoubtedly in favour of it. Doctors John Hunter, Lettsome, Huck, and Sims, and some others, assure us that they employed it with success. The first of these, Dr. John Hunter, was well qualified to give an opinion on the subject. He had received a full and ample education both in medicine and surgery. He had been physician to the Fleet for many years, and had seen a great variety of climates, and at last resided in London, where he was much respected,—p. 18-19.

This is strong testimony, yet such is preconceived opinion that Dr. Crichton manfully argues against it. A pupil of Cullen's, and imbued with Cullen's views, and what Andrew Duncan, jun., calls, "Cullen's professional scepticism," he would rather be wrong with Cullen than right with all the world beside. Yet is he no servile disciple; and when he does throw off the Cullenian shackles, he is both a reformer and a liberal physician,—the latter a character so rare, that when we do meet, we cannot avoid paying it homage.

Among a host of writers whose evidence could be collected in support of the early exhibition of bark in typhoid and petechial fevers, there is none more valuable than that of Bruce, because, unlike medical men, he had imbibed no theoretical doctrine to clog his experimental inquiries. At Masuah, a bay on the Red Sea, at the bottom of which is the miserable town of Arkeeko, violent fevers, called *nedad*, attack the inhabitants, and generally prove fatal on the third day. The native method of treating this fever is thus described:—"If a patient survives till the fifth day, he very often recovers by drinking water only, and throwing a quantity of cold water upon him, even in his bed, where he is permitted to lie without attempting to make him dry, or change his bed, till another deluge adds to the first." (*Bruce's Travels* [abridged], 18mo. *Halifax*, 1840, *p.* 126.)—Thus, it would seem that the vaunted discovery of Priessnitz is only the adoption of a practice common among a barbarous sept on the arid shores of the Bay of Masuah. In England, it is usual to award the credit of the cold affusion in fever solely to Dr. Currie, of Liverpool, but our author recalls to our attention a case of fever cured by cold water, reported in the *Eph. Nat. Curios. decad. iij. Ann. iij. Obs.* 48, and thinks it "probable that Celsus employed this remedy in some febrile disorders." Dr. Wright, however, who practised in the parish of St. Elizabeth, in Jamaica, and whose acquirements as a botanist were very great, published a paper on the cure of fever by the cold affusion, in the 7th vol. of the *Lond. Med. Journ.*, long before Dr. Currie's work appeared. The honor, therefore, of the discovery or revival of the practice, for which sponging, as being more convenient, has been substituted, is due in this country solely to Dr. Wright.—But to return to the subject of Dr. Clarke's treatment, Bruce, or rather his abridger, writes in the same page,—

There is no remedy so sovereign here as the bark; but it must be given in very different times and manner from those pursued in Europe. Were a physician to take time to prepare his patient for the bark, by first giving him purgatives, he would be dead of the fever before his preparation was completed. Immediately when a nausea or aversion to eat, and an unusual, but not painful, sensation along the spine, comes on, no time is then to be lost; small doses of the bark must be frequently repeated, and perfect abstinence enjoined, unless from copious draughts of cold water. The second or third dose of bark, if any quantity is swallowed, never fails to purge, and if this evacuation is copious, the patient rarely dies; but on the contrary, his recovery is generally rapid. Moderate purging then, is for the most part to be adopted; and rice is a much better food than fruit."—p. 126-7.

Dr. F. S. Stuart, whose "Memoirs" were published in the *Monthly Magazine*, for Feb 1815, seems to have been extremely successful in fever, and his treatment differed very little from that of Bruce. Stuart, too, was a man who experienced vast vicissitudes, and visited numerous places within the tropics, and was well qualified to offer an opinion. In Admiral Christian's fleet, in 1795-6, then on the voyage to St. Domingo, he was wrecked three times, when upwards of 5,000 men were lost, and one-sixth only of 400 sail returned to England. He was afterwards at the capture of St. Lucia, at that of Martinique, and again at St Domingo, when 7,600 British soldiers, and as

ny seamen, died of the yellow fever, (i.e., bad food, and worse medical treatment.*) hart was not on the staff, and had little or hing to do with the general treatment, and, erefore, should not share the blame of this nstrous and horrible sacrifice of human life. his department he was fortunate, and states treatment to have been—

"Five grains of the tartarized antimony† and e table-spoonful of soft sugar, dissolved in fifteen ble-spoonsful of boiling water, one of which is ken every fifteen or twenty minutes, until it has erated three distinct times, when an immense antity of acrid, called viscid, bile is evacuated, d the patient immediately relieved. Toast and ater with nitre (*nitrate of potass*) is used for mmon drink, and an ounce of *natron vitriolatum* Glauber's salts—*sulph sodæ*) in it on the second third day, after which bark in port wine, during state of convalescence, has constantly completed e recovery."

This treatment is very similar to that of larke, Millar, Stevens, and such as we ourlf found highly efficacious in the treatment of oldiers, sailors, and civilians, during many ears' practice in the tropics. But we should xtend this article to another number, did we note all that we might say on this subject. Ve shall only add a few remarks on the treatnent of Lind, to which, we must express our urprize, Dr. Crichton has not alluded.

Lind's treatment was,—Ipecacum, to relieve he stomach—then salt of hartshorn (carb. mmon.) 5 grs, laudanum. 15 drops. At other imes, 5 grs. of camphor, every four hours, vith vinegar‡ and whey enemata, were recommended with these. If they failed, he listered. He says, "sixteen out of twenty will be next morning entirely free from heat, headache, pain, and fever." Twenty-four or hirty-six hours after, he gave vitriolated tarar (sulph. potass), nitre (nitrate of potass) vas also exhibited, but he preferred it in glysters. Antimonials were employed by him, and Contrayerva and Virginia snake-root (2 drams of each, macerated for four or five hours n a pint of boiling water, then strained, and wo ounces every fourth or sixth hour), and nock also he freely gave. Bark was freely exhibited during the second remission, "as ll my care during the fever was to cleanse the *primæ viæ*."—p. 65.

We must now bring our remarks on this very interesting work of Dr. Crichton's to a conclusion, dissatisfied with ourself for having added so little to the vast store of knowledge which the author has communicated, but highly satisfied with the manner in which he has spoken "on the doctrine and treatment of continued fevers of a typhoid character."

The chapter relating to "Insanity," and to the "Non-Mercurial Treatment of Syphilis," are important, and require more time and space for their consideration than we can at present afford. However, from the labour which we have bestowed on the "Commentaries on Medicine," the estimation in which we hold this volume will be manifest to our readers. It should be (with Stevens) in the library of every medical man in the East and West Indies, and to European practitioners it will ever be found a safe and excellent work of reference.

* The seamen are predisposed to fever from the nature of their food, which is salted, and often *putrid*, without vegetables.—*Lind. Treat. of Put. Remit. Marsh. Fev.*, 8vo. *Edinb.* 1776.—p. 26.

† A very common purgative in that sluggish fever of Jamaica, which is characterized by many of the symptoms of hepatitis, is, 1 grain of opium, 5 of antimonial powder, and 6 of calomel, and we have been assured by those who have tried this combination, that, though a slow purgative, its effects are very beneficial. Not having tried it ourself, we cannot offer any opinion.

‡ The exhibition of vinegar in any form in fever is extremely doubtful, if not hurtful.—*See Stevens.*

PERISCOPE OF THE WEEK.

IMPROVED METHOD OF ADMINISTERING COD LIVER OIL.—Dr. Ure suggests the adoption of cod livers as a diet for patients who are recommended to take the oil. To prevent loss during cooking, he recommends the livers to be immersed entire in boiling water, to which a sufficient quantity of salt has been added, and to raise the boiling point to about 220 deg. Fahr. The sudden application of this high temperature coagulates the albumen of the liver, and prevents the escape of the oil. When the liver is cut, the oil exudes, and mashed potato may be used as a vehicle. Dr. Ure informs the *Pharmaceutic Journal*, that having been advised to take cod liver oil, he found the nauseous flavour very objectionable, until he contrived the above plan, which he finds to answer extremely well.

BISULPHURET OF CARBON. Dr. Turnbull, whose system of using hydrocyanic acid for the eye, we noticed No. 109, Vol. V., says he has now abandoned that remedy, for bisulphuret of carbon. He puts a drachm into a bottle (containing a small piece of sponge) of about 2 oz. size having a mouth precisely fitted to the eye, and with a ground-glass stopper. He applies the vapour to the closed eyelid; its effect is to contract the pupil, but in what form of disease it should be used, the Doctor says not. He says he uses the same vapour with good effect for the reduction of indurated lymphatic glands. The rationale is thus given. The carbon in the vapour permeates the cuticle, and comes in contact with the oxygen, in the vessels and which is conveyed through the frame by inspiration and otherwise, and thereby forms carbonic acid gas, which evolves heat in the ratio of the quantity consumed by the oxygen. Liebeg is quoted as his authority.

INSANITY. — SIZE OF THE HEAD AND BRAIN.—To find how far the development of the intellectual faculties is influenced by the size of the brain, M. Parchappe, physician to the Lunatic Asylum, Rouen, has carefully examined a great many individuals, first measuring the head in the living subject, and then measuring the head and weighing the brain of the same individual when dead; and noticing every circumstance of sex, age, stature, health, intellect, &c., which was likely to throw new light on the subject. The facts observed by the author amount to 341; or 169 heads measured, 58 skulls measured, 22 skulls guaged, 95 brains weighed. The principal conclusions drawn from these facts, considered in every point of view connected with size (the influence of form being reserved), are—*Size of Head*: The size of the head is much smaller in the female than in the male, not only *en masse*, but in all the separate diameters. The weight of the cranium also is less in the female. —*Age*; The volume of the head does not seem to be limited by the period at which the general growth of the body ceases; the head appears to enlarge gradually up to the age of 60 years. The increase of size shows itself almost exclusively in the horizontal circular development of the head, and depends chiefly on enlargement of the frontal sinuses. After 60 years of age the size of the head diminishes; the weight of the skull also diminishes in old age.—*Stature*; In tall men the head is larger than in small persons.—*Idiotcy*: The head is much smaller in born idiots and fools than in persons of natural mental powers.—*Development of Intelligence*: The intelligence bears no proportion to the size of the head in fools and idiots But on comparing the average of size of 10 heads of men of superior intellect with that of 10 heads of persons whose faculties were below par, the advantage was clearly on the side of the former In men a certain size of head is necessary for a proper development of the intellect, but beyond this we find no necessary connection between the volume of the head and the development of the intellect.—*Race*: The Caucasian race is superior to all others with respect to the length of the head and the size of the frontal and occipital regions. The most powerful causes which influence the size of the head are sex, race, stature, and idiotcy; the development of the intellect is the least influential. —*Mean size of head in both sexes*: In 22 men and 18 women; intelligence normal; age 30 to 50 for men; 25 to 50 for females.

		Males.	Fem.
Antero-posterior diameter		186.8	174.5
Lateral		142.2	136.2
Vertical	Antero-posterior curve	347.5	340.5
	Lateral curve	356.7	340.5
Horizontal	Anterior curve	301.8	288.2
	Posterior curve	297.8	249.5
		1612.8	1529.4

Size of Brain.—Sex: The comparative weight of the brain, in 94 persons of both sexes, gave an average in favour of the male; the capacity of the cranium, measured in 30 skulls belonging to both sexes, was also less in the female. —*Age*: The author's observations lead him to conclude that the brain continues to increase up to the age of 40; it remains stationary to 70, and then begins to decline.—*Stature*: In both sexes the weight of the brain is evidently in relation to the stature.—*Mean weight of brain (from 30 to 60 years)*.

	Brain	Cerebrum	Cereblm	Pons and Med Ob
Males, 13.	1.342 kil.*	1.175	.160	.15
Females, 9	1.229 "	1.062	.133	.13

Relation between the side of the Head and that of the Brain: As the thickness of the occipital bone is subject to much variation, and the size of the frontal sinuses cannot be determined, it is impossible to arrive at any exact relation between the volume of the head and the form or weight of the brain.—*Disease of the Brain in Insanity*: There is no cerebral disease which can be regarded as the essential lesion of insanity; the following are those most frequently found:—Ecchymosis under the arachnoid and pointed injection of a part of the cortical surface, with or without softening; extensive softening of the middle portion of the cortical substance; adherence of the pia mater to the brain; rosy, lilac, or purple color of the cortical substance; atrophy of the convolutions; induration of the brain.

PRODUCTION OF FAT.—M. Dumas gives briefly on this subject the results of some experiments. M. Liebig thus expresses himself: "A lean goose weighing four pounds will gain five pounds in weight within thirty-six days, during which it consumes twenty-four pounds of maize; at the expiration of this time the animal yields three pounds and a half of fat. It is evident that the fat is not derived from the nutriment, for maize contains only 1-1000th part of fatty matter." The authority of M. Liebeg is so great, says M. D., that M. Payen and myself have for a long time sought after the fattening principle of maize, for agriculturists know from experience that a bushel of maize, weighing about twenty to twenty-two pounds, will furnish two pounds of fatty mat-

* The kilogramme is 2,205 lbs. avoirdupois.

ter. The experiments which we have made, prove, contrary to the opinion of M. Liebig, that maize contains 9 per cent of a yellow-oil, about five ounces of which I lay before the Academy. Hence, in eating twenty-four pounds of maize, a goose takes in two pounds and a half of fatty matter, and we need not be astonished at the animals furnishing three pounds and a half, counting the fat which it had originally. Hay contains 2 per cent. of fatty matter, and our experiments prove that cattle, while being fattened, and milch cows always contains less fat than the elements which they have consumed. With respect to the latter, however, the butter represents very nearly the proportion of fatty principle contained in the food of the cow, at least for the two substances just mentioned.

Galvanic and Nervous Influences.—The following curious experiment of M. Matteucci, has been repeated several times with success. Two frogs were prepared; from one the skin was removed; in the other there was merely left a single leg with a long nervous filament attached to it; the filament was then placed across the thigh of the first frog, and, on passing a galvanic current through the latter, so as to make its muscles contract, the leg of the second frog also contracted. When a plate of gold was interposed between the thigh of one frog, and the nervous filament of the other, the communication of electric influence between the two animals was interrupted, and no contraction took place; but a leaf of paper did not produce the same effect. The phenomenon now mentioned occurred in pigeons also.

The Causes and Nature of Inflammation.—Dr. Marshall Hall gives the following as his idea of the circulation: He views the veins, heart, and arteries, as the mere machinery by which the blood is conveyed to those vessels or channels in which the real object and functions of the circulation are performed. In and by these channels the various tissues, with the exception of the non-vascular, are irrigated, and functions which may be compared to those of an irrigated meadow are accomplished; aeration takes place in the pulmonic; nutrition, secretion, &c., in the systemic.—The true capillary vessels, or blood-channels: the veins and arteries are arboriform. The former resembling the roots, the latter the branches, of a shrub or tree. They are linear. The minute arteries in the web of the frog never anastomose; the veins very rarely. They pursue their course over the tissues. The blood-channels, on the contrary, unite and divide continually, pursuing no linear course, but a course modelled, as it were, upon the minute structure of the part, and therefore peculiar to it. There is no proof that these are distinct vessels; many facts lead, on the contrary, to the opinion that they are mere channels formed in the tissues.—The pulmonic and systemic blood-channels: these, with the mesenteric, and indeed with those of each and every tissue, are peculiar and characteristic; a fact described and depicted in an essay on the circulation many years ago, and recently particularly brought into notice. Function of the blood-channels: this is one of irrigation. As from the internal surface of the stomach and intestines, so from that of the blood-channels exosmosis takes place, and nutrient and secernal vessels arise, and perform their various and appropriate functions.—The intermediate position of the blood-channels: the blood-channels are placed immediatly between the arteries and veins, and between these and the various nutrient, secernent, and absorbent vessels. M. Berres, of Vienna, has called them the vasa intermedia. The influence of the nervous system is exerted on the heart, the secernent vessels, &c., and in a secondary manner only on the blood-channels, and probably on the minute arteries, and certainly on the minute veins.—Non-vascular parts are nourished by endosmosis; a process apparently influenced by the degree of energy of the circulation.—The author now came to the first phenomenon of inflammation: this, judging from the circulation and the effects of physical and chemical agents, as seen under the microscope, appears to be adherence of the blood corpuscules to the internal surface of the blood-channels, induced by a physical change in the blood, or in that surface. Hence, obstruction to the flow of blood, and hence—inflammation and its phenomena.—If we place a ligature on an artery or a vein, the phenomena produced, are hypertrophy of the vessels tied; hypercrisis, or augmented secretion, according to a new-old doctrine; hyperexosmosis, &c., &c. Are not these the identical phenomena of inflammation. Have we not enlarged and new vessels; secretions or separations from the blood, of serum, lymph, pus,—and effusion of blood itself, in ecchymosis?—But, further, the blood itself is changed sometimes as the cause, sometimes as the effect of inflammation. In the latter case we have the buffy coat, and augmented fibrine. We have, also, augmented tolerance of bloodletting, mercury, antimony, &c.—(Dr. Marshall Hall has an oddly "coincidental" knack of discovering the discoveries of other people—a trait only equalled in oddity by the intrepid ignorance he assumes as to every thing of importance done by Herbert Mayo, Bell, Majendie, Sprengel, Boerhaave, and other *generally* well known physiologists. Dr. Copland so completely restored the main chattel in this appropriation to its rightful owner Sprengel, at a recent meeting of the Medical Society, that nothing is left to us here, but to express a hope that Dr. Hall will see the wisdom of not casting suspicion on what is truly valuable in his labours, by discoveries which all his equals were already acquainted with, announced with a bold complacency, and combatted for, with a peevish and fretful perverseness, both alike, far below the real worth of his truly powerful mind. Sir Fretful Plagiary could acknowledge a coincidence in the same good thing being thought of by two good minds. What a golden age of peace would visit the scientific world if Marshall Hall would be but one half as frank? Ed.)

Transfusion of Blood.—A man 38 years of age, was seized with an hæmoptysis, which continued so long and so violent, that the only means of saving his life appeared to be by supplying the loss of blood by transfusion. On the fifth day after the attack a canula was introduced into the median vein of his left arm; a syringe, previously heated, was filled with blood drawn from the jugular vein of *a goat*, and about 5 ounces were injected into the vein of the man. Immediately he complained of a feeling of oppression; but this soon afterwards went off. An attack of phlebitis came on next day, but was subdued in eight days, by means of cold applications alone. His strength from this day returned, and at the end of three months he was able to resume his usual occupation. It is remarked, as the interesting point of this case, that it proves that the injection of the blood of one animal into the veins of another, is not necessarily fatal.

Preservation of Leeches. — To pure clay is added as much pure water as will make it so plastic as to be easily formed into irregular shaped balls, two inches and a half in diameter. These are placed into a square deep wooden box, or a five gallon keg. The leeches when put in, creep down the sides of the balls of clay, and remain. Leeches kept in this way will at once lay hold. The balls must be renewed weekly.

Lung Tubercles.—Mr. Addison gives the following as the brief results of his researches on the formation of tubercles in the lungs.—The blood, at all times, contains two distinct kinds of corpuscules—the one red, the other colourless. The colourless corpuscles are highly organised vesicles or cells formed from the central portion of the red corpuscles. They combine with, or adhere to, the tissues through which the minute currents of the blood circulate, and become cells, performing different functions, and assuming different forms, in various parts of the body, in accordance with the primitive law regulating the development of the organism. Thus all kinds of epithelial cells are formed of colourless blood corpuscles, and each cell performs its own function quite independent of those by which it is surrounded.—Pus corpuscles are partially formed cellt; they may be seen in all stages of development, from colourless blood corpuscles in the serum of a blister, to large granulated vesicles, und well-formed epithelial cells in cutaneous diseases. The colourless blood corpuscles have an equally important share in forming "the results of inflammation," as they have in administering to nutrition.—When solely in consequence of their excess, their normal development ceases, they become pus corpuscles; but when they exercise an independent activity they give rise to specific forms of disease.—All the objects composing a tubercle of the lungs originate from colourless blood corpuscules. A tubercular disease of the lung is in all respects analogous to a chronic eruption of the skin (*lepra, psoriasis* and *acne*); the varieties and complications of the one are neither greater nor more numerous than those of the other. The colourless blood and pus corpuscle of man; inner vesicle of the red corpuscle, and the colourless corpuscle or lymph globule of the batrachia; the polygastric animalcules; the pollen grain of phenogamous plants; the the spore of epiphyllous fungi, are all analogous in their structure to each other; they are granulated cells, which may be dissected by Liquor Potassæ.

Kiesteine.—The discovery of a peculiar principle in the urine of pregnant females, by the existence of which a gravid state of the uterus could always be diagnosticated, was announced by M. Nauche, in the year 1831, to the Society of Practical Medicine at Paris. It is a gelatino-albuminous product, and is separated from the other elements by rest alone. M. Nauche stated, that if the urine be exposed for a few days in a glass, the kiesteine shows itself at the surface in the form of specks and oblong filaments, which unite in a pellicle or scum, a line in thickness. A portion of this sinks to the bottom of the vessel, and forms there a whitish deposit of a milky appearance; the rest remains on the surface, adheres to the sides of the glass, and is converted into a solid membraniform substance. M. Eguisier, who followed him, describes the pellicle as whitish, opaline, and somewhat granulated; it has sufficient consistency to admit of being lifted up with some care by its edges. Dr. Golding Bird considers it to be an imperfect caseous matter, mixed with crystals of the ammoniacal phosphate of magnesia, and, pursuing an idea of Professor Burdach, of Konigsburg, that the elements of the milk existing in the circulation may, during certain conditions, be eliminated, and not finding an outlet by the mammæ, be again taken up and excreted by the kidneys, he supposes such elements to enter into the constitution of the kiesteinic pellicle. His experiments were founded on the observation of about thirty cases. Eguisier is of opinion that kiesteine is an invariable attendant of preg-

nancy, and so well marked in its distinctive characters, as to prevent its being readily confounded with others. Becquerel, however, could not discover it in the urine of three pregnant women which he analysed.—As these writers made their observations on not more than sixty cases altogether, Dr. Kane, while one of the resident physicians at the Philadelphia Hospital, availed himself of the opportunities afforded him by his position, to institute a series of experiments on the subject, the result of which are as follows:—1. That the kiesteine is not peculiar to pregnancy, but may occur whenever the lacteal elements are secreted without a free discharge at the mammæ; 2, that though sometimes obscurely developed, and occasionally simulated by other pellicles, it is generally distinguishable from all others; 3, that where pregnancy is possible, the exhibition of a clearly defined kiesteinic pellicle is one of the least equivocal proofs of that condition; and, 4, that when this pellicle is not found in the more advanced stages of supposed pregnancy, the probabilities, if the female be otherwise healthy, are as twenty to one that the prognosis is incorrect. Dr. Kane has been unable to determine the nature of kiesteine by the aid of chemistry; he could not detect in it a notable quantity of either caseum or albumen. The urine was faintly acid up to the period of disintegration, when it underwent the ammoniacal development, and became markedly alkaline. The pellicle, examined in a microscope, possessing a magnifying power of 100 diameters, exhibited a well-defined series of flakes of a darkish yellow colour, made up apparently of minute granules, closely resembling, but rather more flattened than, the granules of the colostrum.

SAFETY EXPLOSIONS IN COAL MINES.—Mr. Murray gives in the *Gateshead Observer* the following method as obviating the use of the safety lamp in preserving a salubrious atmosphere for the miner, and being extremely economic.—Let a copper conducting wire, traversing the avenues and recesses of the mine, form the circuit, connecting the poles of a Smee's Voltaic Battery. This copper wire is interrupted at intervals by uniting wires of platinum; and these platinum wires—say about three-eighths of an inch long and one hundredth of an inch in diameter—form the several nuclei, or centres, of wire-gauze cages—each cage having a double fold of wire-gauze. On each immersion of the voltaic arrangement into diluted sulphuric acid, the platinum wires would be simultaneously ignited through out the entire extent of the circuit, and the gas safely exploded and consumed. A Smee's battery of very small dimensions would suffice; and this might be repeated at specific intervals.

MEDICAL NEWS.

MEDICAL ACTION.—An action to recover a bill for medical attendance was tried on the 25th ult. at Barnstaple sessions. The plaintiff, Mr. Joce, was non-suited on the ground that the certificate of the Apothecaries' Company did not prove itself. Evidence was given that it was like the usual certificates; but no sufficient evidence was adduced that it was the genuine seal. A question was put to us some time since, to which we responded to the above effect: a contemporary, to the same question, we noticed, gave a different reply; and hence probably this unfortunate result. It cannot be too well known, that since 1826, the Seal of the Company has ceased to be a proof of the genuineness of the document, unless proved by a party having actual knowledge of the original seal, who should be an officer of the society.

CHEAPNESS OF MEDICAL CORONERS.—We believe, says Mr. Wakley, that the disbursements of the *attorney* coroner are one-third greater than those of the *medical* coroner. And why? *Because the former is obliged to incur more than three times as much expense for the payment of medical witnesses.* Frequently, be it observed, when an attorney coroner has heard medical testimony, he is *guided* by it, *led* by it, *controuled* by it, just as it has fallen from the lips of the witness, without having *had* a clear and distinct knowledge of any one medical sentence that has been uttered. (To do Mr. Wakley justice he is sufficiently economical in his payment of medical men for their testimony. If the act for the payment of medical witnesses be not a dead letter, it is no fault of his. The hon. member contrives to attend twice as many inquests as other coroners think necessary (the payment being per inquest), and to pay medical men, by his own confession three times less! So much for the disinterested friend of the profession! Our readers will do well to remark, that though the other coroners pay three times more for medical testimony their expenses exceed his but by *one-third.*)

APOTHECARIES' HALL.

Licentiates admitted Thursday, October, 13, 1842:—

J. W. Beresford, Macclesfield; W. E. Taylor; W. Fraser, Sunderland; H. S. Lyford, Winchester; W. Sewell, Bowness; J. Corrie, Thornton, Bradford; S. S. Perkins, Exeter; T. Ager, Castle Hedingham.

Friday, October 14, 1842.

T. Peat; J. Moore; H. D. Scholfield; J. Rhodes; O. Boyd; C. Telfair; J. Vickerman; J. I. Acheson; J. M. Best.

ADVERTISEMENTS.

Just published, a New Work on Mental and Bodily Disease. By Forbes Winslow, Esq., M.R.C.S.L., Author of "The Anatomy of Suicide."

ON THE HEALTH OF BODY AND MIND

BY FORBES WINSLOW, Esq. &c.

CONTENTS:—

1. Early Symptoms and Treatment of Insanity.
2. Metaphysics of Medicine.
3. Wanderings of the Imagination.
4. On Longevity.
5. On Malaria.
6. On Cold.
7. On the Art of Being Ill.
8. On Sound.
9. Asphyxia, or Apparent Death from Drowning, Hanging, &c.
10. Physiology of Death.
11. Psychological Medicine.
12. Influence of the Mind in the Production of Disease.

The principal portion of the work has a relation to the early indications and treatment of derangement of mind, particularly of suicidal mania. Mr. Winslow's object is to establish that in every case of insanity there is a well marked premonitory stage which is not admitted to be insanity, but in which the patient is conscious of the coming on of madness.

London: HENRY RENSHAW, 356, Strand, and of all medical and other Booksellers in town or country.

MEDICAL BOOKS.—Armstrong's Morbid

Anatomy of the Stomach and Bowels, 16 plates, finely colored, 4to. cloth, £1 1s. (pub. at £3 3s.); Morgagni's Seats and Causes of Diseases Investigated by Anatomy, translated by Alexander, 3 vols. 4to., calf, £1 10s.; Paxton's Introduction to the Study of Human Anatomy, numerous engravings, 2 vols. 8vo., cloth, 10s.; Hunter's Natural History and Diseases of the Human Teeth, plates, 4to., bds., 14s.; Good's Study of Medicine, by Cooper, 5 vols. 8vo., bds., £1 10s.; Scarpa on Hernia, by Wishart, 11 plates, 8vo., bds., 4s.; Louis's Pathological Researches on Phthisis, translated by Cowan, 8vo., bds. 6s. (pub. at 12s.); Ramsay's Anatomy of the Heart, Cranium, and Brain, 15 coloured plates, 4to., bds., 8s. 6d.; Heurteloup's Principles of Lithotrity, plates, 8vo., bds., 5s. (pub. at 20s.); Lee's (Dr. R.) Researches on the Pathology and Treatment of Some of the Most Important Diseases of Women, plates, 8vo., cloth, 4s. 6d.; Kay's Physiology, Pathology, and Treatment of Asphyxia, 8vo. cloth, 2s. 6d., 1834; Dunglison's Human Physiology, numerous engravings, 2 vols. 8vo. bound, 14s., Philadelphia, 1836; Andral's Clinique Médicale, 5 vols. 8vo., half calf, 15s., 1823.

S. & E. NOCK, 15, TOTTENHAM COURT,
South side of the New Road, near Gower Street.

NEW EDITIONS OF MR. CURTIS'S WORKS ON THE EAR.

A TREATISE on the DISEASES of

the EAR, with CASES and PLATES. Sixth Edition, price 7s. 6d.

"The best treatise on the ear extant."—Metropolitan Magazine.

2. An ESSAY on the DEAF and DUMB, with Cases and Plates. Second Edition, price 10s. 6d.

"Mr. Curtis's cases and suggestions deserve consideration."—Medico Chirurgical Review.

3. The PRESENT STATE of AURAL SURGERY, containing Remarks on Deafness, &c., founded on the experience of upwards of 30,000 cases, with Strictures on Catheterism and the alleged Cure of Throat Deafness by excision of the Tonsils and Uvula. Second Edition, price 1s. 6d.

"Interesting to the profession and all classes."—Literary Gazette.

"The author appears well versed in its diseases."—Lancet.

"Mr. Curtis has done more for the cure of diseases of the ear than any other man living."—Monthly Magazine.

Longman and Co.; and J. Churchill, Princes Street, Soho.

MESSRS. WHITTAKER & Co., AVE MARIA LANE, LONDON,
Have just published, price [illegible],

INFUSORIA. The History of Infusoria, living

and fossil, with descriptions of all the known species, arranged after Dr. Ehrenberg, and 500 coloured illustrations. By ANDREW PRITCHARD, M.R.I.

MICROSCOPIC ILLUSTRATIONS. A new Edition, enlarged, price 1s. 6d., with descriptions of the Achromatic, Polarizing, and other Microscopes, and ample instructions for use.

This work is the only practical treatise on the use of Modern Microscopes extant, price 2s. 6d.

ENGLISH PATENTS, being a Register of all those granted in the *Arts, Manufactures*, CHEMISTRY, *Agriculture*, &c., in 1841, with copious Index, and an account of the new Act to secure designs on articles of manufacture.—Also, Second Edition, price 1s.,

A LIST OF 2,000 MICROSCOPIC OBJECTS, with Remarks on the Circulation in Animals and Plants seen under the Microscope.

MEDICAL WORKS

Published by Mr. MURRAY.

I.

ESSAYS and ORATIONS on some of the MOST IMPORTANT DISEASES. By SIR HENRY HALFORD, Bart. M.D. 3d edition, enlarged. Fcap. 8vo., 6s. 6d.

II.

The SANATIVE INFLUENCE of CLIMATE. With an Account of the best Places of Resort for Invalids in England, the South of Europe, &c. By SIR JAMES CLARK, Bart., M.D. 3d edition, with considerable Additions. Post 8vo., 10s. 6d.

III.

REMARKS on MEDICAL REFORM, in a Letter addressed to the Right Hon. SIR JAMES GRAHAM, Bart. By SIR JAMES CLARK, Bart. M.D. 8vo., 1s.

IV.

An ACCOUNT of the MOST IMPORTANT DISEASES PECULIAR to WOMEN. By the late ROBERT GOOCH, M.D. 2d edition, 8vo., 12s.

V.

PATHOLOGICAL and PRACTICAL RESEARCHES on DISEASES of the STOMACH, the INTESTINAL CANAL, the LIVER, and other VISCERA of the ABDOMEN. By JOHN ABERCROMBIE, M.D. 3d edition, enlarged, Fcap. 8vo. 6s.

VI.

ESSAYS on the MOST IMPORTANT DISEASES of WOMEN. By ROBERT FERGUSSON, M.D. Post 8vo., 9s. 6d.

VII.

FOOD, and its INFLUENCE on HEALTH and DISEASE, or an ACCOUNT of the EFFECTS of DIFFERENT KINDS of ALIMENT on the HUMAN BODY. With DIETETIC RULES for the PRESERVATION of HEALTH. By MATTHEW TRUMAN, M.D. Post 8vo., 7s. 6d.

VIII.

OBSERVATIONS on the HEALTHY and DISEASED PROPERTIES of the BLOOD. By WILLIAM STEVENS, M.D. 8vo. [illegible]

IX.

ELEMENTS of the PATHOLOGY of the HUMAN MIND. By THOMAS MAYO, M.D. Fcap. 8vo., 5s. 6d.

JOHN MURRAY, Albemarle Street.

On the 1st and 15th of each month, price 6d. (Stamped 7d.)

THE CHEMICAL GAZETTE; or, Journal

of Practical Chemistry, in all its applications to Pharmacy, Arts and Manufactures. Conducted by WILLIAM FRANCIS and HENRY CROFT, late Students in the Universities of Berlin and Giessen. The object of this Journal is to furnish those engaged in Chemistry, the druggist, the chemical assistant, the manufacturer, with a comprehensive view of all that occurs on the continent as well as in this country, relating to the chemical part of their pursuits.

R. and J. E. TAYLOR, Red Lion Court, Fleet-street, and all Booksellers.

IMPORTANT TO AUTHORS, PUBLISHERS, AND ARTISTS.

BOOKS may now be Illustrated in a very su-

perior manner, securing to Artists a faithful copy of their designs to the minutest touch, and at a very great saving of expense, by adopting PALMER'S PATENT IMPROVEMENTS in producing SURFACE PRINTING BLOCKS, which are printed like Wood-Cuts with the type. The most elaborate drawing can, by these means, in a few days be made ready for the press. A great variety of specimens may be seen, and every information afforded to Authors, Publishers, and Artists, on personal application to the Patentee, at 103, Newgate-street, London, between 9 and 10 o'clock, A.M.

MOSLEY'S METALLIC PENS.—The ex-

traordinary patronage which these celebrated PENS have met with since their first introduction to the public, is a convincing proof of their decided superiority. For ease and smoothness in writing they are equal in every respect to the quill, while their great durability, combined with their cheapness, cannot fail to recommend them to the notice of merchants, bankers, and others, where time and legible writing are appreciated. Another proof of their sterling qualities is the circumstance of their being used in most of the Government Establishments, where only articles of a superior description are admitted. To guard against the many spurious imitations that are palmed upon the public, every genuine pen is stamped "Richard Mosley and Co., London." These pens are sold by all stationers and other respectable pen-dealers throughout the kingdom, and wholesale at No. 8, HATTON GARDEN.

SMOKY CHIMNEYS CURED AT ONCE.

THE Advertisers have discovered the cause of

Weak Draughts, Down-ward Current, &c., and they undertake, in a few hours, to perfect the draughts of the most faulty chimneys. The cure is effected by a simple and permanent process, at a stated moderate charge when perfect. W. H. PHILLIPS & Co., Patentees, 41, Bloomsbury-square. References in all parts of London. N.B. Contracts made to warm Conservatories and Greenhouses in a novel manner at one fourth the common cost.

ONE SHILLING the LOT! at LAVENNE'S,

6, JOHN STREET, OXFORD STREET. 1 quire of large note satin gilt paper embossed with any INITIALS, coronets, or fancy medallion; 2 dozen of satin envelopes, also stamped; and 25 fancy wafers (the whole for 1s.); or a ream of the same paper, 10 dozen of envelopes, large or small, and 500 new wafers for 10s. A great variety of fancy note paper from 6d. per quire to £3 12s. New French motto wafers at 1s. per hundred. Fancy envelopes, scented sealing wax, scented note paper, &c. &c.

RIFLE SHOOTING.—Wm. TILKE, Super-

intendent of the NATIONAL BATHS, WESTMINSTER ROAD, has the honour to inform his Patrons, Friends and the Public, that he has arranged with [illegible] for to rent the splendid RIFLE PISTOL GALLERY [illegible] long by [illegible] wide, unequalled in length, together with [illegible] suite of Billiard and Refreshment Rooms for the Winter [illegible], where they may depend from the great alterations upon his extension to ensure every attention, amusement, and comfort. The whole range of buildings cheerfully and brilliantly lighted with Gas. Terms, by day, per doz. shots, 1s. By Gas light, [illegible] Gentlemen and Gun makers accommodated with a trial of their Rifles and Fowling pieces from Ten till Four o'clock at 1s. per hour. Every opportunity afforded to ladies and gentlemen simultaneously by Mr. Tilke, who is always on the premises, and will be most happy to shew the Baths to ladies in particular, who have not had that opportunity in the summer in consequence of the Bathing.

Gloves, Singlesticks and Foils for the amusement of gentlemen.

ROYAL ADELAIDE GALLERY.

LECTURES on CHEMISTRY, &c., by Dr.

AIKIN. Dr. Aikin commenced a Course of Lectures on Chemistry in the Laboratory of the Institution, on WEDNESDAY, October 5th, 1842, at 10 o'clock a.m., and will continue them every morning at the same hour.

The course will consist of upwards of 100 Lectures, and is intended for persons wishing to study Chemistry, either as a branch of medical education, or in its application to Arts, Manufactures, &c. The modes of assaying and analysing inorganic bodies will be shewn and explained. A considerable part of the course will be devoted to organic Chemistry, &c., and a full account given of the late discoveries by continental observers. Fee, Five Guineas.

On the same day a series of Lectures on Practical Chemistry will be commenced, in which the Pupils will have opportunities of performing experiments, applying tests, and becoming familiar with manipulation. Each practical course will comprise Sixty Lessons, and be given at hours to suit the convenience of students. Fee, Three Guineas.

One Course will be especially devoted to Chemists and Druggists.

Extended laboratory practice for not less than three months, at the rate of Fifty Guineas per Annum.

Assays and Analyzes conducted by the Chemist personally. Mineral Waters from 10s. 6d. to £1 1s. each. Agricultural and other Analyses on moderate terms.

Gentlemen wishing to carry out especial investigations, or experiments for perfecting inventions, may have the use of apparatus and the assistance of the Chemist, by applying to the Secretary.

PORCELAIN LETTERS. HUGHES and

CLARK, Sole Agents for Yates's Patent Porcelain Projecting Letters and Figures, for Shop Fronts, Hotels, Public Buildings, &c. &c., 158, Strand, (adjoining King's College.) These Letters are recommended with perfect confidence as the most durable, beautiful, and economical ever offered to the public. No repainting or regilding can ever become necessary, as (unlike either Wood, Metallic, or Composition) they are always new, and so extremely durable that after the wear of half a century they would be equally brilliant as on the day they were first put up. They are warranted neither to Blister, Warp, Crack, or Corrode, as, unlike every composition, [illegible] to resist the action of the weather and temperature of any climate. They can be fixed on either Wood, Stone, or Brick. Patterns will be forwarded for inspection to any part of London and the vicinity. N.B.—Unglazed Letters for Painting or Gilding.

Leeds Public Dispensary.

TWO ASSISTANT APOTHECARIES are

wanted for this Institution, whose duties will be to Dispense and Assist in Visiting. Notice is hereby given, That the MEDICAL OFFICERS will proceed to the ELECTION, on THURSDAY the 17th of NOVEMBER NEXT. Candidates are required to attend in person at the Dispensary, on MONDAY the 14th of NOVEMBER, at Twelve o'clock, when Testimonials of Moral and Professional Character are to be produced.

Further Particulars may be known on application to the Medical Officers of the Institution, or to Mr. Lee, at the Dispensary.

Oct. 27, 1842. CHAS. TOL, Secretary.

Opportunity will be afforded of attending the Lectures at the Leeds School of Medicine which qualifies for Examination at the Royal College of Surgeons, Apothecaries' Hall, &c.

LOAN of his Imperial and Royal Majesty the

EMPEROR of AUSTRIA, of the year 1839. Capital, Thirty Millions of Florins, Convention Money, to be reimbursed with 71,500 bonds. The NEXT DISTRIBUTION will take place on the 1st of December, 1842, consisting of the following considerable sums: One prize of 250,000 florins, one of 50,000 florins, one of 15,000 florins, one of 10,000 florins, one of 8,000 florins, one of 6,000 florins, two of 5,000 florins, two of 2,000 florins, three of 1,500 florins, five of 1,200 florins, five of 1,100 florins, five of 1,000 florins, six of 800 florins, ten of 800 florins, twenty of 700 florins, forty three of 600 florins, and five hundred and ninety-three of 500 florins; together 700 premiums, amounting to 721,700 florins, convention money. One bond, £3; six bonds, £15; one fifth, 12s. An official bulletin of the result will be sent to the shareholders.

For prospectus, and to obtain bonds, apply to A. J. Strauss, Banker, Frankfort-on-the-Maine, or to John Schultze, Foreign Agent, 32, Villiers-street, Strand, London.

ENGLISH and SCOTTISH LAW FIRE and

LIFE ASSURANCE and LOAN ASSOCIATION.—Established 1839. Offices, 147, Strand, near Somerset-house, and 119, Princes-Street, Edinburgh.

The entire Capital of the Association, amounting to One Million sterling, has been subscribed for, upon which interest at Five per cent. per annum, is regularly paid half-yearly.

This Association, by its constitution, embraces:—

Every description of Risk contingent upon Life and Fire, on terms as moderate as are consistent with safety.

A liberal system of Loan, whether for a term of months or years;

A union of the English and Scotch systems of Assurance, by the removal of all difficulties experienced by parties in England effecting Insurances with offices peculiarly Scotch, and vice versa;

A large Protecting Capital, relieving the assured from all possible responsibility, and guaranteeing, at the same time, a certainty of the prompt settlement of every Claim; while it also admits every Policy-holder, assured for the whole term of life, to a full periodical participation in Two-thirds of the Profits of the Institution.

Individuals possessing real or personal property, officers in the army and navy, clergymen, professional men, merchants, tradesmen, and persons of respectability and character, may, if assured in this office, obtain advances for periods varying from three months to any other specified period, and in amounts of £50 and upwards, upon the following security:—

Upon Freehold and Leasehold property in England, and the corresponding description of property in Scotland, either to be assigned or deposited upon equitable mortgage, upon reversions, annuities, pensions, or any other description of assignable property or income, of adequate value.

Upon Personal Security, by the borrower procuring two or more responsible securities, to join him in a bond or other security for repayment, and on condition of the life of one of the obligants being assured.

Upon the security of Policies effected by parties with this Association, according to the value at the time of the loan.

By allowing the Assured to retain a portion of their Premiums at interest. J. S. PIDGEON, Actuary.

BRITANNIA LIFE ASSURANCE COMPANY.

1, Princes-street, Bank, London.

This Institution is empowered by a Special Act of Parliament, (IV. Vict. cap. IX.) and is so constituted as to afford the benefits of Life Assurance in their fullest extent to Policy-Holders, and to present greater facilities and accommodation than are usually offered by other Companies. The decided superiority of its plan, and its claim to public preference and support, have been proved incontestably, by its extraordinary and unprecedented success.

*** Assurances may either be effected by parties on their own Lives, or by parties interested therein on the Lives of others.

The effect of an Assurance on a person's own life is to create at once a Property in Reversion, which can by no other means be realised. Take, for instance, the case of a person at the age of Thirty, who by the payment of £5. 3s. 4d. to the Britannia Life Assurance Company, can become at once possessed of a bequeathable property, amounting to £1000, subject only to the condition of his continuing the same payment quarterly during the remainder of his life,—a condition which may be fulfilled by the mere saving of EIGHT SHILLINGS weekly in his expenditure. Thus, by the exertion of a very slight degree of economy,—such, indeed, as can scarcely be felt as an inconvenience, he may at once realize a capital of £1000, which he can bequeath or dispose of in any way he may think proper.

Detailed Prospectuses, and every requisite information as to the mode of effecting Assurances, may be obtained at the Office.

PETER MORRISON, Resident Director.

A Board of Directors attend daily at 2 o'clock for the despatch of business.

SOLUT. MAGNES. BICARB. Dr. WILKIN-

SON, of Bath, whose well-known familiarity with Practical Chemistry entitle his opinion to respect, says:—

"A bottle of the Fluid Magnesia, sold as 'Fluid Magnesia,' was sent to me for Analysation by a Chemist in this City; I found it to contain Seven Grains of Magnesia and [illegible] to the ounce, whilst yours yielded Seventeen Grains of [illegible] to the ounce. I can conscientiously bear testimony to the correctness of the above result.

(Signed) "C. H. WILKINSON, M.D."

"Dated October 2nd, 1840."

To Mr. C. DINNEFORD, Bond-street, London.

The above conclusions have been further corroborated by Professor BRANDE, of the Royal Institution.

Dr. PARIS, author of the Pharmacologia, and Mr. MURRAY, of Dublin, who also examined and reported on Sir James Murray's compound.

It has also received the sanction of SIR HENRY HALFORD, Bart., President of the Royal College of Physicians, and the most distinguished Members of every branch of the Medical Profession.

Sold in Jars (for dispensing only) containing [illegible], at [illegible] each, by the usual respectable Wholesale Houses, or direct from the Proprietor.

London: Printed and Published by JOHN MCGOWAN CARFRAE, 19, Essex Street, Strand, in the Parish of St. Clements Danes, Westminster, in the County of Middlesex.—November 12th, 1842.

AGENTS.—Maclachlan & Son, Edinburgh; Simms & Son, Bath; Wilmer and Smith, Liverpool; Fannin & Co., Dublin.

THE MEDICAL TIMES

A Journal of English and Foreign Medicine and Medical Affairs.

No. 165. Vol. VII. LONDON, SATURDAY, NOVEMBER 19, 1842. PRICE FOURPENCE. STAMPED EDITION, 5D.

For the convenience of Subscribers in remote places, the Weekly Numbers are re-issued in Monthly Parts, stitched in a Wrapper, and forwarded with the Magazines. Orders for the Stamped Edition (10s. 10d. per Half-year, Post-free in advance,) are received by any Bookseller or Newsman, or may be directed to J. A. Carfrae, Esq., at the Medical Times Office, (late Lancet Office), London.

SUMMARY.

ON THE LAWS OF THE DEVELOPMENT OF ORGANS; OR, TRANSCENDENTAL ANATOMY APPLIED TO PHYSIOLOGY.

By E. R. A. SERRES, Member of the Institute, of the Academy of Medicine, Professor to the Museum of Natural History, Paris, &c., &c., &c.

Summary.—On the Primitive Division of Organs—their mode of increase—Formation of organs by juxta-position—On the Morphology of organs—Views on the fundamental element of form in organic and inorganic bodies—On the law of homozygy, or association of organisms—Relation between the constituent elements of an organ and its mere form, considered in reference to organogeny—On the true meaning of an organite—Mode of discovering in the adult, traces of organites, &c.

Our last remarks teach how theories follow one another in the sciences; how a system once predominating, and widely spread, leaves behind it opinions which survive long after the hypotheses which engendered them have ceased to be received. The pre-existence of germs ended in producing a final division between organic and inorganic bodies; these latter, in fact, being devoid of germs, were necessarily separated from organized beings; but while exaggerating their differences, their analogies were overlooked. The sciences were divided into two classes, and an eternal divorce pronounced between them. The increase of inorganic bodies takes place by juxta-position, the molecules of augmentation placing themselves, according to certain laws, around the primitive body. That of organized bodies, on the contrary, was considered to take place by intus-susception, the primitive tissue enlarging or dilating itself. Such was the generally received opinion. M. Chevreul, however, remarked that this expression though applicable to the total process of development in living bodies, ceased to be so when considering the immediate constituents of the tissues, their increase being explicable only by juxta-position, as that of inorganic bodies. According to this celebrated chemist, the phenomena of nutrition consist in the juxta-position of new organic molecules upon the old ones.

The same law which presides over molecular nutrition, in like manner governs the primitive formation of the tissues and the increase of organs. Thus the blastodermic membrane in the embryo is originally composed of two layers placed in juxta-position, the internal mucous, the external serous; subsequently, however, a vascular layer becomes interposed between them, so that this membrane is definitively constituted by the juxta-position of three layers. Now it is from these three layers that all the organic systems arise, and, whatever may be their varieties of form and of function, the mechanism of their construction is a repetition of that of the blastodermic membrane. Thus is the osseous system produced in the first instance by a layer of fibres, upon which new layers become successively placed, and which, according to Malpighi, might be compared to the leaves of a book. In like manner, the osseous tissue of the tooth is constituted by a succession of fibrous lamellæ, not unlike the osseous layers; and upon the primary osseous layer we shall find deposited, by juxta-position, the vitreous layer. The osseous fibres, moreover, do not extend continuously along the entire length of the bone; but when examined by the microscope, they appear to be formed by a series of fibrillæ super-added the one to the extremity of the other. The elongation of bones and of teeth takes place then by super-position, and their increase in breadth by juxta-position.

Although differing greatly from the osseous system, the formation of the nervous system takes place in the same manner. On examining by the microscope the two layers of nervous matter originally constituting *the spinal marrow*, we observe that the fibres composing them appear interrupted at various spaces, instead of forming a continuous fibre from one extremity of the spinal marrow to the other. The increase in length as well as in breadth of the spinal marrow is then similar to that of bone. It is by a successive juxta-position of nervous layers that it acquires its future volume.

With regard to the vascular system, which forms a continuous whole closed at all parts, this mode of formation at first sight appears repugnant to nature. Still, during the primitive formation of the embryonic circulation in the omphalo-mesenteric membrane, we may see the capillary vessels, scattered in small isolated plexuses, join themselves one to another, thus producing branches, and finally trunks, and this lengthening takes place by a succession of hollow fibres, joined one to the extremity of the other. While this elongation is taking place, a similar increase in breadth is being accomplished by a juxta-position of layers, the number of which remains yet undetermined.

But above all others, the muscular system appears subjected to this general mode of formation. Every one knows that the force of a muscle is proportionate to the number of fibres constituting it; that the muscular fibre is interrupted in its length, at various distances, by fibrous intersections, of which the *recti* muscles of the abdomen afford an example. This fact is distinctly shown by the microscope in the infusoria, in the larvæ of insects, and in the fibrous bands constituting the muscles of the annelida, of the earth worm, and especially of the leech. Lastly, this arrangement may be seen with the naked eye in the muscular bands entering into the structure of the intestinal canal. A remarkable feature in this aggregation of parts is, that union takes place only among similar structures: thus nerves join themselves to nerves, arteries to arteries, and so on; but never do we see arteries and veins unite themselves with nerves, or the elements of the osseous fibre associate themselves with those of the muscle. The cause of this phenomenon is, however, perfectly unknown to us.

We now come to the *form* of organs. In the theory of pre-existences the form of organs was at all periods of their development considered immutable; thus placing organogeny in direct opposition with inorganic bodies. As in the latter the straight line is the fundamental element of form, so was the curved line made that of the form of organized bodies; the surface of inorganic bodies being angular, that of organic bodies was necessarily rounded: in a word, as the forms of the first are all derived from combinations of the straight line, so were those of the second from combinations of the curved line. These facts are essentially true if we consider organs or organized beings, merely at the last term of their development. Then the rounded and circular forms predominate in all parts of the animal organization. The bones are rounded; their heads most frequently globular. The muscles elliptical, orbicular, or perfectly circular. The viscera are all more or less of a semi-elliptic form.

But passing to the earlier stages of development, the circular lines are lost. The spherical, circular, or globular forms do not exist; they are the result of the concourse of two or more lines, the juxta-position of which forms the curve, the cavity, the sinus, the hole, in a word all the parts which in the normal condition of the perfect animal are more or less circular. We thus arrive at a conclusion totally opposite to the preceding, that there is not, in the organization of animals and of man, a single line primitively circular. The form of the greater number of muscles results from the succession of an immense number of almost straight fibres implanted, like the feathers of a quill, upon a central stem. In the orbicular muscles, no single fibre makes the circuit of the muscle. The curve is produced by a succession of almost rectilinear fibres, forming a polygonal half ring; for the circular muscles are always the result of the union of two half muscles. So do we find the *orbitar* cavity formed by the junction of five bones. The *acetabulum*, the *glenoid* cavity of the scapula, that of the temporal bone, &c., all result from a similar mechanism. Finally, we may instance the vertebral ring, forming an enclosure round the spinal marrow, and which is composed of four or six primitive lines, each constituting bony nuclei in the young embryo. In tracing the development of any organ, we find it originally composed of several fragments; its permanent form resulting from the association of these primitive materials. The form of the liver in man and the mammifera results from the fusion into a single organ of the three or four lobes originally representing it. The prostate surrounding the root of the urethra is primitively composed of two, three, or four lobes. The kidney, which in the adult man constitutes a simple organ, is in the embryo represented by eight or ten separate kidneys, small but perfectly distinct, and which in the progress of development become blended or united together into a single organ.

Thus are the organisms, at their commencement, in the very young embryo, composed of various fragments, divided and sub-divided *ad infinitum*, when we penetrate into their intimate nature. This is the first condition of their existence. The final end of developments is to unite together, and to associate these separate and disjointed parts. Now, this union of the elements of organisms takes place in two ways; either by association or by incorporation. In association, the elements of organisms become joined together; in incorporation they do more than join, they become intimately united or blended together. These two conditions of organic transformation are not entirely analogous, for in association, the similar elements although joined together are separated by a dissimilar tissue, whilst in incorporation the similar elements are in immediate contact. It happens in some cases, through the progress of development, that organisms, in the first instance associated, become eventually united by incorporation; this change is, however, always preceded by the transformation of the dissimilar tissue which becomes homogenous, and which thus favours and compels incorporation. I will give an example:—The vertebral column is formed by the association of twenty-four vertebræ, separated one from another by the interposition of a dissimilar fibro-cartilage, which remains up to extreme old age. During the whole course of natural life, these vertebræ remain united by association and not by incorporation. The sacrum which terminates the column inferiorly, is itself formed by five vertebræ, associated at first by the interposition of a similar fibro-cartilage. But long before puberty, the fibro-cartilage becomes ossified, the five vertebræ become united by incorporation, and form but a single bone, which,

however, preserves the generic characters of it mingled elements. Thus the vertebral column is an associated organism, the sacrum an organism united by incorporation.

In union by association, the organisms preserve an independance which is but little affected by their composition. The muscular fibre, which by its multiplied associations constitutes muscles of such various forms and sizes, experiences from these associations no alteration in its characters; it is the same with the nervous system: the same also in a great measure, with the intimate structure of the osseous system. In incorporation, on the contrary, the elements which become united together lose by this fact a part of the character peculiar to them. The sacral vertebræ, for instance, in man, lose by incorporation, some of the characters of the adjoining lumbar vertebræ: it follows, therefore, that the less the elements of organisms are associated together, the more they retain their original character, and that the more intimate their combination, the more their dissimilitude increases. This dissimilitude is, however, more apparent than real; for, by disassociating the elements of organisms,—that is to say, by restoring to them the independance which they have lost by their union —we also restore them the characters masked by incorporation. Now association and incorporation being the two generating processes of the *form* of organs, it follows that the variations of form, however numerous or diversified, affect but slightly the nature or essence of the organism. An instance of this may be found in the serous membranes, which vary so much one from another in form and size, but are in their true nature so identical. All primitively represent a bag closed at all parts, a sac without an opening; all are destined to protect and envelope certain organs. The essence, the radical of every serous membrane is then the same—a bag; the accessory is the form here and there assumed so as to accommodate itself to the inequalities of the organs upon which it is spread. Thus we may readily conceive that the bag embracing the heart and the large vessels proceeding from its base, must have a much more complicated form than that surrounding the lung; or that the *peritoneum*, enveloping organs so various in configuration, extent, and size, must be very different in form to the *tunica vaginalis testis*, or the synovial membrane of a tendon.

The manner in which these various forms are produced is another point, upon which much speculation has been expended. Borden supposed them to be engendered by friction; Bichat, in refuting this idea, substituted that of the pre-existence of these membranes, as well as of the organs themselves. The true explanation, however, is, that they are formed conjointly with the organs; that each bag is at first separated from the organ which corresponds to it; that by the progress of development, the organ draws nearer to it; that it finally becomes placed in contact with it, and gradually buried within its folds. We now perceive how the serous membranes borrow from the organs which they cover their various forms; but this diversity of form changes neither their structure nor function,—it disguises their resemblance, but does not alter it. There is here, then, but a repetition of the common law; an organic element once given, nature varies and modifies in a thousand ways its combinations, by diversifying its mode of association. But before association, the elements of organisms are isolated and separated one from another, and it is only in this state of isolation and independence that they preserve the plenitude of their peculiar existence and distinctive characters. A striking example of this is furnished by the glandular system. In the earlier stages of the human embryo, the elements composing this system are found divided and subdivided *ad infinitum*; but by the progress of development, these elements become united and combined in various ways, producing bodies differing greatly in form and appearance. On tracing them, however, to their earliest formation, we find these glands reduced to a simple, primitive element—the generator, as it were, of the whole glandular system. This element is a little bag endowed with a small duct, something similar to the gall bladder in miniature. This little bag, with some modifications, is universally found in the composition of glands: whether in the *glandulæ solitariæ* of the intestines, or in the *glandulæ agminatæ, conglobatæ, conglomeratæ*, &c.

A remark which has doubtless struck anatomists, is, that the various processes adopted in anatomy for the purpose of unfolding the structure of organisms, are merely directed towards reducing the organs to that primitive state of simplicity possessed by them at their first formation. Association has united and as it were confounded the elements entering into their composition; disassociation isolates and separates them anew; art acts in an inverse sense to nature. Whether we employ water or exposure to air; whether we adopt maceration, or the simple action of acids or of alkalies, as an aid in our minute dissections, we merely destroy the cement binding together the constituent elements of organisms, and thus reduce nature to its primitive condition.

Association then tends to group together the constituent elements of the organisms, uniting one with another parts which have a common and independent action. This aggregation of the elements of organisms is expressed by the term *organite*. A few examples will render the meaning of this term intelligible. The vertebra is primitively composed of four points of ossification —two for the lateral processes, and two for the body; the occiput has eight, the sphenoid twelve: each of these points, considered separately, is an *organite*. The fœtal kidney is frequently composed originally of six small kidneys, the associated tubes of each of which terminate in a distinct *papilla*; this small *papilla*, the tubes converging towards it and the body resulting from this association, constitute an *organite* for the kidney. So also with the testicle, the liver, the prostate, &c.

Incorporation, which we may consider as association in a more advanced stage, unites and groups together the *organites*, in the same way that association groups and unites the constituent elements of parts; it brings into a state of unity the various organites constituting an organ. Thus it is by incorporation that the several points of ossification join together in forming a bone, or that the various *organites* of the prostate, the kidney, &c., form in the adult a body of so uniform an appearance. While on this subject I may remark, that the variations of form produced by the incorporation of *organites* are subjected to the same conditions as those resulting from the association of the elements of organisms. Thus the numerous varieties of teeth met with throughout vertebrated animals, are reducible to two dental *organites*—the incisor and the canine. The molares, so different in appearance to either of these, result entirely from the combination of these two dental radicals. We see, then, as an inevitable consequence, that neither the form nor the number of organs are absolute attributes of organization: we can only consider as such the constituent elements of organisms, and from the diversity of their combinations result those different aspects under which they are presented to the eyes of the observer.

We have previously shown, that the possibility of reducing organs to the primitive simplicity of their composition, formed one of the fundamental proofs of association. Is such the case with incorporation? Can we find in the adult traces of these *organites*, the incorporation of which has formed the organ? The examination of their *solidescence* discovers to us these new facts. We may perceive, on viewing the structure of their parts, that their consistence varies in different points, showing, in some measure, the nature of their composition: for by comparing the anatomy of the embryo with that of the adult, we shall observe that the most consistent parts correspond exactly to the organites which have become incorporated, so that we may find upon organs as many solidescent zones as there were primitively separate organites. This law becomes of great value in attempting the classification of those bones or remains belonging to animals long since extinct.

The parts which enter into the composition of an animal are thus divided, not only during the first stage of their existence, but also when association has already commenced their combination; and they do not entirely lose this state of division until incorporation is accomplished. Each of these elements possesses a determinate form; in one place it is fibrous, in another it is composed of a bag closed at all points; sometimes this bag opens externally, at other times it is transformed into a small blind canal (as the cœcum). These forms, special to each organic element, change and modify themselves by their association, sometimes assuming an elongated, sometimes a radiated, or even an elliptical form, in the compounds or organites to which they give rise. Lastly, incorporation in its turn, combines these organites, producing by their coalition the normal forms presented by parts in their complete developement. Thus the fixed point is the organic element, whilst the forms of its combinations may, and in fact do, offer infinite varieties. It is then association, of which incorporation is but a more advanced stage, which is the principle of the morphogeny of organisms: it unites that which was divided, and by uniting it engenders form. To be enabled more fully to appreciate these organogenic facts, we should compare them with the other hypotheses which have been broached. To what, in fact, was morphogeny reduced by the theory of pre-existences? To a simple developement. The form of organs being considered invariable, the only difference acknowledged between the embryo and the adult was with regard to size. The cranium was considered but a vertebra dilated or expanded by the progress of its developements. The brain was regarded as the product of an efflorescence or shooting forward of the corpora pyramidalia and olivaria; the radiated fibres of which, traversing the grey or cortical substance, proceeded to form the hemispheres and commissures. Nothing could be more simple than this manner of considering organogeny, but it was found to be in manifest contradiction with facts. I will confine myself to one example: Take the brain of an animal with a double cerebellum, but with simple cerebral hemispheres; on examining its base, we find four corpora pyramidalia and four olivaria, the radiations of which traverse a double annular protuberance. Take, on the other hand, a brain with four cerebral hemispheres and a simple cerebellum, as in the genus *polypus*; the base presents, as in the normal state, but two corpora olivaria, two pyramidalia, and one annular protuberance. Now, if the cerebral lobes were but the efflorescence of the corpora pyramidalia and olivaria; if these bodies were really their roots, who does not perceive that when there exist, as in the first case, four corpora olivaria and four pyramidalia, traversing two annular protuberances, there should necessarily be developed four cerebral lobes? still there are but two. And again, in the second case, would not the existence of four cerebral hemispheres necessarily require the presence of four corpora olivaria, four pyramidalia, and a double protuberance? The protuberance is, however, simple, and we find but one corpus olivare and one pyramidale on each side. Is not this a most decisive contradiction to the above hypothesis? We shall, moreover, as we proceed, find this theory of organic preformations overwhelmed by the mass of facts accumulated against it.

Fuligokali.—This is a preparation of soot and potassa, which is prepared in the following manner:—℞ caustic potassa, 20 grammes; powdered soot, 100 do.; distilled water, 2 do.; boil for an hour, cool, dilute with water to facilitate filtration; filter, evaporate, dry, in order to obtain the fuligokali in a black powder or in scales, and put it in dry and warm flasks. For sulphuretted fuligokali:—℞ fuligokali, 60 grammes; caustic potassa, 14 do.; sulphur, 4 do.; heat the sulphur and the potassa with a little water; after the sulphur is dissolved, add the fuligokali, evaporate, dry, &c. Fuligokali has been tried by M. Gilbert on his patients at *Hopital Saint-Louis*, both internally and externally. He made with 30 grammes of lead, and 1 or 2 grammes of fuligokali, a pommade in which he recognized resolutive, detersive and slightly stimulant properties.

COURSE OF LECTURES ON THE THEORY AND PRACTICE OF MEDICINE.

Delivered by C. J. B. WILLIAMS, M.D., F.R.S., Professor of the Practice of Medicine, and of Clinical Medicine, at University College.

GENTLEMEN,—At our last meeting we were engaged with the changes occurring in connection with the vascular system, in inflammatory fever. But this is not the only system affected, for the *nerves* are involved also. There are changes observable, too, in the characters of the blood itself; —it becomes altered, so as to cause cupping and the existence of the buffy coat;—the nature and meaning of these alterations I explained to you on a former occasion. It has been supposed by some that the changes arising in the blood may be the cause of fever,—but this is unquestionably erroneous, seeing that the fever *precedes* the appearance of the buffy coat. The buffy coat may occur also *without* fever; this has frequently been noticed in cases of pregnancy. There is no doubt, however, that the blood, when thus changed, may keep up the irritation, and modify the character of the secretions. Too much fibrin in the blood produces general excitement in the system. When the fibrin is diseased, a cachectic state is sure to supervene. The existence of pus in the circulation will be attended with hectic fever. Other matters may also cause similar symptoms, such as sugar, in diabetes,—the poisonous matter in cases of gangrene is also, as we before noticed, pervaded through the system. The blood, again, is the medium through which the critical discharges, attendant upon the resolution of fevers, are effected. When inflammatory fever arises from constitutional causes, as cold, the symptoms bear a very strong resemblance to idiopathic fever,—thus, the shivering, depression, loss of appetite, &c., would leave us quite uncertain whether an idiopathic fever, or some local inflammation, was about to follow. In the former kind of fever the secernent and nervous systems are affected in a much more serious degree than in simple inflammatory fever. There are few cases in which the latter species of derangement proceeds to a greater extent than in inflammation of the testicles. The fever is generally proportioned to the amount of local inflammation present; but there are exceptions even here. In tonsillitis, for example, there is very frequently rather considerable preceding fever, although the inflammation itself may be comparatively trifling. The fever usually runs high in young and plethoric subjects, and in those who are easily excitable; it is also rather severe in persons who are not very susceptible of its influence, but still in whom it has been determined. The fever is low in old people, and in those who possess little blood and are phlegmatic. Its intensity is much modified by the part which is the seat of inflammation. It is high, for example, in fibrous and serous membranes, as in the various fasciæ, and in the pleura and peritoneum. It is high, also, in phlegmonous inflammation. In inflammation of the stomach it has a rather low tendency. When mucous membranes are affected, the fever assumes a sort of mixed character—also, when cellular tissue is affected, or when the mischief is seated in large joints, &c.,—this depends in a great measure upon the effects of the products upon the secretions. In persons who have been habituated to hard drinking, inflammation is generally of a low type; also in cases where violent shocks have occurred; and, also, in cases arising from the influence of animal poisons,—all these have a tendency to depress. We thus see that much depends upon the previous habits of the patient, upon the seat of the inflammation, and upon the nature of the causes that have determined its occurrence.

We now proceed to a brief consideration of the *local* symptoms of inflammation—and sometimes these precede the constitutional, in cases where the cause has been local. It is not at all uncommon for the constitutional symptoms to mask, as it were, for a time the development of the local ones, so that the latter become much more manifest as the former decline. The first of the local phenomena that we may notice, is *redness*—this, as well as heat, will be in proportion to the vascularity of the tissue; that is to say, the more vascular the tissue is in its natural state, the greater amount of redness it will exhibit when subjected to inflammation,—thus we find the skin (not the epidermis, of course) becoming very red when inflamed. The redness is also sometimes intensely marked in inflammation of mucous membranes,—it disappears, generally, after death. I told you, before, that the redness is due to the increase and tortuosity of the vessels; it is owing, also, in many cases, to the existence of patches of *extravasated* blood. This hæmorrhagic redness is distinguished from simple inflammatory redness, by the former being usually found in the form of a patch; whereas, in inflammation, the blood being contained *within* the vessels gives rise to a *striated* appearance. Again, the redness that is caused by inflammation or congestion, may be temporarily removed by *pressure*, but this exerts no influence in altering the colour which is produced by extravasation. The redness observed in serous membranes, as a result of inflammation, is much less intense than in mucous membranes—the dots that are seen generally exist in the vessels of the subserous tissue. In fibrous tissues the vessels are still less distinct. In parenchymata, the redness is considerable. The colour is greatest during the time of determination and congestion, for, when more advanced, and effusion has taken place, the vessels become relieved, and the redness is diminished. Another pretty constant result of inflammatory action, is *swelling*, which is commonly in proportion to the complexity of the tissue in which the inflammation occurs. It arises, in the earlier stages, from the size of the vessels, and afterwards from the effusion that is produced—this is well seen in cases of erysipelas. The special seats of swelling are the cellular tissue and parenchymata; these, you will remember, are the textures in which *pain* is generally at its *minimum*, so that pain and swelling may be said to exist in inverse proportions. Swelling is very rarely observed in serous membranes, for all the effusion that their inflammation produces, takes place within their cavities. In some cases, only parts of organs become swollen—in others, the whole substance is enlarged, as in the liver, and in glands generally, especially the lymphatics. Swelling in the skin is well seen in urticaria. It becomes very great in the eye-lids, scrotum, and also in the rima glottidis; in fact, in all *loose* tissues. Another phenomenon is *heat*—to this I have before alluded. I told you that it is doubtful whether it is produced in the inflamed part, or whether it is carried there by the increased quantity of blood. Hunter found the latter method to hold good in a case of hydrocele, in which he noticed that the temperature of the scrotum, and that in the axilla, were precisely equal. The heat is easily ascertained by means of a small thermometer. The next symptom of inflammation is *pain*—arising from exalted sensibility or from the pressure of distension. In a low degree, it is only itching. The pain will be much modified by the nature of the tissue in which the inflammation exists—inflammation of a nerve, for example, will, of course, be very painful. The degree of pain will depend much upon the *tension* that is produced in parts—thus, any effusion taking place under a strong fascia, which, not yielding, is attended with much tension, will, of necessity, cause great pain; this is the case in tendinous structures generally. Much suffering is experienced when inflammation attacks the periosteum. Again, in parts where there is much distension, as in inflammatory toothache, great pain is felt, on account of the very unyielding nature of the surrounding structure. Also, in inflammation of the internal ear, when effusion takes place. But in loose parts, where the tissue is of such a character as to admit of easy distension, it will be naturally expected that much less pain should accompany the inflammatory process. In the intestinal canal, for instance, there may be inflammation with very little pain; or, indeed, without any actual pain at all, so long as the parts are kept in a state of rest, and not allowed to suffer pressure; but then, so soon as food is allowed to pass along the inflamed portion, very great distress may be occasioned. In parenchymata, there is not, usually, much pain attendant on inflammation. In serous membranes, the degree of pain is variable —sometimes being considerable, and sometimes very slight; it is generally greater in them than in mucous membranes, because the substance of the latter is much more yielding, as in parenchymata, there is little tension. Where the sensibility is great, pain may be experienced on the application of pressure over the inflamed part, although, without pressure, no suffering may have been complained of. In addition to the *general* results and features of inflammation, as occurring in the various classes of tissue, to which I have now briefly called your attention, you will be prepared to expect that there should also be some *special* modifications produced in connection with the proper *functions* of *particular* organs, and these may be called *functional* symptoms; thus, when the heart (or rather the pericardium) is the seat of inflammation, we find the action of the organ materially increased, giving rise to palpitation —afterwards, when the inflammation has continued some time, and fluid is effused into the pericardium, the action of the heart becomes diminished and oppressed, and the whole circulating system is affected in proportion. Again, in inflammation of the lungs, the functions of respiration will, of course, be interfered with to a greater or less amount, and it is this *functional* impairment that renders the disease so formidable. In many cases of inflammation, the effects are not confined to the precise limits of the local mischief, but *other* parts, at some distance from the inflamed organ, suffer also, and present what are called *sympathetic* indications, or symptoms—thus, inflammation in the liver, is often accompanied by pains in the shoulders, especially under the right shoulder. Another example of sympathy is, the retraction of the testis that occurs in inflammation of the kidneys; also the pain, affecting the glans penis in cases of inflammation of the bladder. Sympathy is also manifested by the occurrence of vomiting in many cases where parts at a distance from the stomach are the seats of injury or disease. I must here caution you against coming to the conclusion that *inflammation* is present in all cases where *pain* is complained of, and also against concluding that inflammation is *not* present, because pain is *absent*. Nothing is more common than to find great pain arising from what is termed *irritation*, in nervous subjects, without the least trace of anything like inflammation being discoverable—and, on the other hand, we not unfrequently see cases where inflammation *does* exist, but where, if we trusted to the symptoms of pain alone, as indicating the inflammation, we should be led into the most glaring and dangerous mistakes. It is in torpid subjects, whose nervous system is unusually obtuse, that we generally find *latent* inflammations occurring; i.e., inflammation, unattended with the ordinary symptoms of its existence. In persons, who are highly sensitive, or, in other words, are *nervous*, the very slightest causes may give rise to excessive pain, without the presence of inflammation,—these cases are, as a general rule, easily distinguished from true inflammations, by the absence, in the former cases, of *heat*, fulness of pulse, and the ordinary constitutional symptoms that inflammation is known to produce. When inflammation eludes our touch and vision, we may be greatly aided by sound—thus, if we wish to ascertain the size of the liver, as affected by alterations in the quantity of blood contained in it, we may do so by the use of *percussion*, which will indicate, to an experienced person, the precise dimensions. The changes, sensible to the ear, that are effected in the organs of the chest, especially by inflammation, &c., will be fully considered at a future period. I might have given you other examples of the alteration in the special functions of particular parts, such as diarrhœa in enteritis—constipation in peritonitis—incontinence of urine in cystitis—spasms in inflammation of the spinal chord—and delirium and coma in phrenitis. A good exemplification of sympathetic affection is found in the reference of pain to the rectum, constituting tenesmus, in cases of inflammation of the colon.

Inflammation has been divided into *acute*, *subacute*, and *chronic*. Hippocrates and Celsus limited the acute to 14 days—after this, to the 24th day, they considered it subacute—and if it continued beyond the 24th they called it chronic.

PRIVATE COURSE OF OPERATIVE SURGERY.

By J. NOTTINGHAM, Esq., Member of the Royal College of Surgeons of London.

LECTURE IV.

HITHERTO our observations relate chiefly to incisions made from without inwards; but we not unfrequently have to make them in the opposite direction, or from within outwards.

In some few operations special incisions of this kind are employed, upon which a great deal depends,—as in dividing the stricture in operations for strangulated hernia, or in the employment of the lithotome caché, when this is chosen for the operation for stone; or in that of the curved bistoury used for dividing the sphincter ani in cases of fistula, the edge and point of which are covered by a sliding guard when the instrument is first introduced; but such incisions, as well as the instruments used in making them, will be noticed in connection with the respective operations for which they are required, and we have here to speak chiefly of the more common incisions made from within outwards, with or without the aid of a director.

Before opening what are called sinuses we should ascertain the direction and extent of the chief canal, as well as of its principal branches, if the probe or director will easily enter the latter, before taking up the bistoury; and it is also desirable to notice whether or no the complete division of every part of the sinus can be effected without injury to any artery, vein, nerve, or other important structure, and to modify our proceedings with a view of leaving them intact.

Where an external opening exists into which the director may be introduced, this instrument is passed through it and pushed to the opposite extremity of the sinus; and then the bistoury, its back resting in the groove of the director, is moved on as far as the latter will carry it. The heel of the bistoury may now be depressed, and its point made to press against the corresponding portion of the integument, through which it is pushed, and the structures in front of it may next be divided by sawing motions of the instrument, or by suddenly drawing it through them.

In some cases the point of the bistoury may be guarded by a bit of bee's wax stuck upon it, or the probe pointed bistoury may be used instead of the one that is sharp at the extremity: and here, as the instrument is not driven through the integument at the farther end of the sinus, its heel must be raised, and in this way its edge made to divide all that is requisite by pressing against the structures between the two extremities of the canal to be laid open.

In laying open some old fistulous canals it is well to be provided with a strong bistoury, or one firm and stiff in the blade; for the density of the sides and textures around such canals is often much greater than that of the neighbouring parts, and will occasionally try the strength of an ordinary instrument.

The opening of canals, such as we now allude to, may require to be made upwards, downwards, to the right hand, or to the left; but the surgeon may generally place himself in such position with regard to the parts to be divided as to effect all that is required to be done, and that without any particular difficulty.

We are occasionally recommended to divide layers of cellular membrane raised over the director, by passing the bistoury through them with its edge downwards, or turned towards the groove of the director, so that by every touch the edge of the instrument is being spoiled and worn off by the iron surface it falls upon. If a man's hand be so unsteady that he find the director a support to him, he may be allowed it as an indulgence; for in such case the bistoury might perhaps have been pushed too far, every now and then endangering parts beyond the bounds of the cellular tissue to be cut through, but in other circumstances we would recommend, that a surgeon should handle his cutting instruments with as much respect for their edges as a joiner would have, who is not caught shaping out a piece of wood with a chisel on the surface of a blacksmith's anvil, and is very apt to complain of the old timber he works upon if he find that its hidden nails are spoiling his saw.

Turn the back of the instrument, then, to the groove of the director, and have mercy upon its edge, and upon the teeth of the bystanders. In cases where very narrow sinuses are met with—so that a director or bistoury of ordinary size can hardly be introduced without at once cutting or lacerating the parts—a very small silver wire may be passed into the canal, when a delicate bistoury is made to follow, the bistoury having a groove on its back, by which it is kept in contact with the wire; the approximation being further ensured by a little bridge crossing the groove, under which the wire was made to glide.

There are instruments made for instrument-makers, and there are instruments made for surgeons,—the latter to be used, the former to be admired. Perhaps the bistoury with a bridge on its back is of the admirable class, and may be regarded as belonging to matters of taste. I remember, however, that Lisfranc would not, on any account, be without such a bistoury in his pocket-case, for I rather think he invented it, as it was spoken of by all his followers, and invariably mentioned by the private teachers of operative surgery, who lectured under his auspices.

In cases where two or more incisions meet at either of their extremities, or cross each other as in the crucial incision, the enclosed flaps or angles of integument have to be raised by dissection, for which good finger nails, forceps, and a scalpel or bistoury are required.

In raising up a piece of integument, we should aim at following the layer of subjacent cellular tissue, not too near the integument, nor yet too near the fascia below, but along what we might call the middle of the layer of reticular membrane, where its net-work is the most loose; such dissection should consist of incisions of the cellular membrane, steering clear of the parts above and below it, which will be much facilitated—if we have the aid of a good assistant, who constantly renders the parts visible to the surgeon—by clearing away the blood with a sponge as fast as it oozes from the divided vessels.

In raising flaps of moderate size (by dissection) the touches of the bistoury may be often made in both directions; first, the edge coming towards the operator, afterwards going away from him—the instrument being turned round at that extremity of the incision which is next to the surgeon. This proceeding is more graceful than repeating the first touch of the knife over and over in the same direction, and is more especially applicable after the crucial or the **V** or **T** incisions have been previously made. Where the texture of the cellular membrane is very loose, the trouble of dissection may be shortened and the pain lessened, by drawing the portion of integument to be raised towards one side, and employing the finger nail or the handle of the scalpel to break through the stretched cellular structure on the other.

In cases where adhesion has taken place, and where (as far as the surgeon is concerned) the reticular membrane might be said to be lost or obliterated, the proceedings with the scalpel must be more careful, and the separate incisions or touches of the instrument will generally require to be shorter.

In some of the operations for hernia, an extraordinary degree of care is required in the employment of the bistoury; the sac must be approached with great caution, as well as the intestine within it; good finger nails, a delicate and educated sense of touch, dissecting forceps with points, that seize easily and hold firmly, will assist us materially in such operations; but to prepare himself more completely for them, the young surgeon should practice that mode of raising bits of cellular membrane with the forceps, and then passing the bistoury horizontally through the texture so raised, which manœuvre is required especially on these occasions; for if the sense of touch be tolerably good, if the surgeon can with the aid of it detect the gliding motion of one layer of serous membrane within the fold of another, and discover the occasional presence of fluid between them, supposing this not to be great enough in quantity to separate widely the sac and the intestines, it will generally be easy to avoid injuring the latter; the main difficulty being to know where we have really arrived at the sac, which requires to be opened; so that, as far as speaking of this particular mode of employing the bistoury is concerned, little need be said beyond a hint about attaining the habit of raising delicate fibres or layers of membrane with the point of the forceps, and then passing the bistoury carefully under the extremity of the other instrument.

We now proceed to offer a few remarks on the subject of punctures, which, to speak of them in a very general way, may be made with large or with small instruments; indeed, some of the instruments made for this purpose are so small as to shield the patient from any injury on almost every occasion, as well as to protect the surgeon from any suspicion of having committed himself—a sort of thing which occasionally happens where a larger instrument has been inconsiderately plunged into a tumour of doubtful character.

The first consideration, then, to be especially attended to, before employing any kind of puncture, is the accurate diagnosis respecting the real state of the parts and the peculiar character of the malady affecting them; and, fortunately, the differences between tumor, abscess, and aneurism, &c. are generally such as to enable one to decide where puncture is perfectly safe, and where it is better to avoid it; yet cases do now and then occur, where such diagnosis is embarrassed; and if, on such occasions, it is impossible, without doubt, to decide, and yet absolutely necessary to act, we had better take the benefit and protection of two opinions, which, in such circumstances, afford the best excuse for a mistake, should this by any chance occur.

The needle, bistoury, lancet and trocar, are amongst the principal instruments used in puncturing; when the needle is employed, the name acupuncturation is admissible on account of the instrument used.

In employing the needle, we should first notice, whether its point be sharp, and also remember, that it must not be so small and weak as to bend under the pressure required to make it pierce the surface and enter the parts to be punctured, or explored; nor so large and thick as to make an aperture in the surface or parts beneath which, might, under any circumstances, be attended with risk.

We may easily suppose that there can be no great difficulty about introducing a needle into any soft part of the body, nor would it be worth the trouble to offer any particular rules for the guidance of so simple an operation. The needle may be introduced either perpendicular to the surface, or with any inclination to it, that the position and condition of parts may require; and should there be any difficulty connected with the density of the structures, or the weakness of the instrument to be overcome, it is better to seize the latter a little nearer to the point than is requisite where the needle enters with little pressure.

Where acupuncturation is employed for the relief of rheumatic or neuralgic complaints, the needles are generally pushed to a greater depth, and require to have such heads of sealing wax, or such handles attached to them as may enable us to withdraw them without the help of any other instrument.

In making punctures with the bistoury, their depth may be measured by the position which the middle finger takes on the right-hand-side of the blade of the instrument; they may be perpendicular to the surface or inclined to it; the latter direction being more particularly required where it is thought fit that the external and deeper parts of the puncture should not correspond, or that the opening may be in any way rendered valvular.

Every one is acquainted with the ordinary method of holding the lancet, in bleeding—the blade turned to a right angle with the haft.

The lancet commonly requires to be inclined to the surface into which we are about to push it; the integument and parts beneath gently stretched and steadied, and the point of the instrument applied, which then receives a gentle pressure from the hand at the other extremity, and transfixes the skin. When an incision is to be made with

the lancet as well as a puncture, the instrument is carried farther on, and then raised at the heel.

Certain precautions are required in the employment of the trocar, which it is easy to forget or to overlook; its introduction should be rendered easy, and the after exit of the fluid not prevented by accidents which have to be guarded against during the operation.

In cases of ascites, where the trocar has to pass through the linea alba, or other part of the abdominal parietes, its introduction will often be much facilitated by previously making a small incision in the integument with the point of a bistoury or lancet; the trocar is then easily glided through the fasciæ and other less resisting structures, and it does not enter the peritoneal cavity with a jerk, or endanger the viscera beyond it. But, suppose that the instrument has a stunted or not a very sharp point, that it is pressed upon the resisting linea alba without a previous touch of the lancet the parts give way to it in a little time, and it often enters suddenly, under the influence of the force exerted and in a manner that the hand of the operator does not seem nicely to measure.

Care should be taken that the further extremity of the canula is not stopped up by contact with the surface of any internal organ, which might prevent the entrance of the fluid we wish to evacuate; the introduction of a director, or some such instrument, through the canula, will answer this purpose; or a second smaller tube, may after the withdrawal of the trocar, be glided into the canula which having apertures in its sides near the further extremity will allow the fluid to pass through them, the extremity being rounded like that of a catheter.

We cannot fail to understand how the trocar is to be handled at the time of its introduction; the handle of it takes its place in the palm of the right hand of the surgeon, who steadies the canula upon it by the pressure of his index finger, and at the same time directs the point of the instrument to the part it is about to transfix; the trocar is then pressed onward, and directed by the hand. As soon as we have the sensation that the instrument has entered the cavity, it is directed to the canula, and the surface through which it passes are steadied with the fingers of the left hand, and the trocar drawn out with the right.

Every one who desires to be adroit in the surgical manipulation of instruments, such as the bistoury, lancet, trocar, or scissors, must take every possible opportunity of practising with them on the dead subject; and as the dead bodies of the lower animals,—which are easily obtained,—will answer many useful purposes connected with this pursuit, we are not to complain of any want of those materials which are essential to our preliminary labours.

REVIEWS.

On Injuries of the Head Affecting the Brain. By G. J. Guthrie, F. R. S., Surgeon to the Westminster Hospital, Opthalmic Hospital, &c. &c. Churchill.

(Concluded from page 109.)

SECOND NOTICE.

In our last number we made some general remarks on the character of this work, and shall now, according to our promise, place a more extended outline of the volume before our readers.

The subject of which our author treats may be subjected to a two-fold division:—1st. Those injuries of the head that produce *concussion* of the brain; and 2d. Those which produce *compression*, or *irritation*, of that organ. As systematic arrangement of the diseases of which he treats seems not to have been the object of our author, the subject is discussed not in the order above indicated, although the undercurrent of arrangement which pervades the volume will permit of such a classification. The whole subject of "*concussion*" is discussed in the short space of thirty-three pages, quarto though they be; yet we have no hesitation in saying that the substance of all that is known, or worth knowing, on the subject, is given in that short space. In the remaining one hundred and twenty pages the subject of "*compression*" is treated of, both as regards principle and practice; and we have numerous interesting cases of this affection resulting *directly* from depressed bone, extravasated blood, foreign bodies—such as balls lodging in the brain; or *indirectly* produced from injuries of the scalp, from erysipelas, or from wounds or operations inducing suppuration under the scull, or fungous growths, or cerebral protrusions through artificial openings in the cranium.

The acknowledged difficulty in forming a just prognosis and diagnosis of all such injuries has induced our author to recur to the physiology of the nervous system, in explanation of the phenomena of lesions of different parts of the brain. Our author justly makes this the starting point of his inquiry, and has given a condensed statement of all the facts which experimental physiology has unfolded, which bear upon this subject. Yet much light cannot be elicited from this source. General conclusions have been deduced regarding the cerebrum, cerebellum, medulla oblongata, and spinal chord, which are valuable so far as they go, and are important, regarding the general or collective functions of each of these parts. Thus it is established that the cerebrum is the seat of intellect, memory, and sensation, and that injuries of the cerebrum affect all these powers; that the cerebellum is the *moderator* of the *movements* of the system; that the medulla oblongata is the seat of *respiration*, and that the spinal chord, with the nerves attached,—the incident, sensitive, and reflex motive nerves,—preside over the acts of ingestion and egestion, retention and exclusion. These are highly valuable facts, and capable of important applications to surgery and medicine, and tend to make us regret that the means that have brought these general facts to light have been ineffective, regarding the functions of the different portions or subdivisions of the cerebrum. Thus enlightened by physiology, our author leads us to the subject of concussion of the brain, regarding the proximate cause of which much obscurity exists. In some instances a bruised, in others a lacerated, state of the brain has been found; but, as in others, no apparent morbid state existed, it is probable that the morbid condition to which the term concussion has been applied exists in a molecular change, which the microscope would be the fit instrument to discover. The *symptoms* of concussion, which are very correctly and vividly described by our author, may be said essentially to consist in a greater or less insensibility—in a diminished state of the circulation—in irregular, though not generally stertorous, breathing—and in a medium, or more frequently, contracted state of the pupil. When death is not the immediate or speedy result of the accident, reaction takes place, and the patient is liable to be cut off by cerebral inflammation. The following mild case will impart a very correct idea of the symptoms and of the proper treatment:—

Frederick Paris, aged 27, a shoemaker, fell from a scaffold 25 feet high, and was admitted into the Westminster Hospital on the 3rd of August at 11 o'clock, two hours after the accident, apparently insensible, the skin clammy and cold, pupils contracted, pulse feeble and irregular, respiration quickened, no relaxation of the sphincters. The head was shaved in order to discover more readily any external injury, but none appeared of consequence, although the scalp could not bear to be touched without the patient showing some signs of uneasiness. The pulse rose to 100, became regular and fuller towards the evening. He spoke incoherently from time to time. A cold lotion was applied to the head. Calomel and colocynth, salts and senna were administered, and, in the evening, he was bled to 12 ounces with the most beneficial effect; he slept, and awoke next morning quite collected, and from this time he gradually recovered, with only a slight giddiness occurring occasionally.

We perfectly agree with Mr. Guthrie, that when the symptoms of reaction set in we should not wait the effects of blisters and purgation, but should have recourse immediately to the lancet; and we are of opinion that if the lancet fail in effecting a cure, no other means can be depended upon. Mr. Guthrie has done good service to surgery by inculcating, both by precept and example, vigorous depletion in these cases; and the *result* of his practice, as given in the work before us, amply justifies the procedure.

After some less important cases of insensibility, arising from intoxication, mimicking the symptoms of concussion and the supervention of *mania* upon injuries of the head, our author proceeds to *compression* of the brain, and has adduced a body of interesting facts from the wide field of his experience, illustrative of almost every variety and modification of such affections. Is the brain compressible, or susceptible of being compressed into a smaller space, is a question not yet decided by physiologists. Our author enters upon the question, and after referring to the various opinions entertained of the intimate structure of the fibres of the brain, leaves the matter where he found it, or rather shirks the question upon that ground; but from the phenomena attending syncope and sanguineous congestion of the brain, thinks that compression may take place, or, at all events, that more blood may exist at one time within the cranium than at another. On this last point we entirely coincide with our author, and it appears to us of no practical moment whether the diminution arise from an absence of blood, or from an abnormal condensation of the cerebral substance. Whatever may be the proximate cause of compression, or state of the brain, in this affection, there cannot be a doubt that the mechanical cause producing it, is adequate to tell both upon the nervous fibre and upon the blood circulating in the viscus,—and thus to have a two-fold influence upon the function of the cerebral organ. But we must hasten to the more surgical part of our subject.

The symptoms of compression from *extravasated blood* are fully and accurately given—a remark that applies to the symptoms of the other kinds of compression, or from other causes. Our author has viewed his subject here, more in detail than in a general or comprehensive manner. We think there are symptoms *common* to compression of the brain, from whatever cause, and others that appertain to the peculiar cause or causes exciting the compression. The symptoms indicative of compression, generally, are insensibility, accompanied with paralysis, convulsions, or twitchings of some parts—dilated pupil, slow pulse, and stertorous breathing, a group of symptoms easily distinguishable from those of concussion, and referable exclusively to simple compression. The *symptoms* again, indicative of *particular causes* of compression, such as fractured and depressed scull, extravasated blood, foreign bodies lodged within the brain, or under the cranium, must be looked for in the history of the case—in the external peculiarities generally of the case rather than in its essential characters. Our author very properly notices the paralysis or convulsions that arise from compression, to be for the most part seated

in the opposite side of the body from that of the injury; and attributes the symptom, along with the numerous authorities he quotes, to the decussation of the fibres of the medulla oblongata. But all the fibres of the medulla oblongata do not cross; and how does it happen that compression should produce in one paralysis, and in another convulsions? Our author has not attempted to solve these problems. We think we can. The very circumstance that *all* the fibres of the medulla oblongata do not decussate, will enable us to explain how the paralysis or convulsions should sometimes be on the same side, at other times on the opposite side from that of the cerebral lesion; and with regard to the supervention of paralysis at one time, and convulsions at another from the same cause, we must recollect, that the fibres of the brain may be affected in a two-fold manner by the compressing cause. The compressing cause may simply irritate the fibres, with which it is in contact, and thus cause convulsions, or the compression may be more intense when paralysis will supervene. Or we may have both paralysis and convulsions existing simultaneously from various degrees of compression induced in different contiguous fibres of the brain: or, lastly, we may have paralysis and convulsions alternately in the same muscles from varying degrees of compression on the same cerebral fibres. This last may take place from the varying state of the circulation of the brain modifying the condition of the compressing cause, and consequently with the corresponding results. But we must proceed to the practical *details* of the author.

Compression of the brain, accompanied with fracture of the cranium in all its modifications and details constitutes the largest portion of the work before us, and we can strongly recommend this part of the work to the careful perusal of our readers. As fractures of the cranium are in themselves not more dangerous than fractures in any other bone (except in so far as such fracture may indirectly or directly affect the brain), our author urges the propriety of not wantonly exposing the bone in our anxiety to ascertain the existence or non-existence of a fracture; for the existence of a fracture does not influence the treatment, unless the case is so urgent as to require or demand the application of the trephine. The following case illustrates the treatment to be followed, whether the fracture is apparent or not:—

A soldier, partly in liquor, received a blow from a spade, in Lisbon, in the beginning of 1813, which cut the upper part of the head across the sagittal suture, and rendered him senseless. He soon recovered, and a slight fissure or fracture, without depression, was discovered on his being brought to the Estrella Hospital. As there were no symptoms indicative of mischief, I desired that his head might be shaved, and the divided parts brought together by sticking plaster; that the head should be kept raised, wet, and cold; that he should be bled to 24 ounces, purged, starved, and kept quiet in a dark room. The next day he said he had slept well, but that his head felt painful, as if something tight was ied around it. Pulse 96, small and hard; bowels not open. Blood was taken from the arm to the amount of 10 ounces, when he appeared ready to faint. Calomel and jalap, followed by Infus. Sennae cum Magnes. Sulphate, were given, and acted well, and he was greatly relieved. The calomel was continued every six hours. In the evening, however, the pain and tightness of the head returned, with a pulse of 110, hard and full, and were again removed by the loss of 24 oz. of blood. He remained easy until the evening of the next or third day, when the pulse quickened to 120, became small and hard, and he complained of severe pain in the head. It was evident that inflammation of the brain, or its membranes, had commenced, and that it must be subdued; he was therefore bled until he fainted, 40 ounces being taken away. This entirely relieved him, and calomel, jalap, senna and salts were again administered, with great effect. On the fourth day he was easy, the pulse 94, soft and full, the mouth being tender from the mercury. The wound did not heal by adhesion, but by granulation; and under the continuance of the starving and purging system he gradually got well without any more bad symptoms, having been saved by the loss of 128 ounces of blood in three days.

When the fracture is complicated, however, with laceration of the middle meningeal artery, or depression of the scull, and the symptoms continue urgent, after the requisite depletory means have been pushed to the full extent, the patient should be trepanned. This is the rule of practice—a rule which gives full effect to depletion, both as a means of preventing evil consequences as well as of cure; and which sanctions the application of the trephine only when that application is imperiously demanded. The depressed fractures that usually demand the application of the trephine are those of adults, more particularly those in which the depressed portions present rough and angular projections to the dura mater, or in which spiculæ of bone penetrate the dura mater or brain, or in which the source of irritation cannot be removed without the application of the instrument. There is one kind of depressed fracture to which we have time only to allude, but which shows the difficulties that surround the subject. We mean depressions of the *inner table*, without fracture of the outer plate of the scull. After collecting the most important cases of this kind on record, our author sums up the practice to be adopted in the following words:—

The records of eighteen centuries have produced but little information on this most interesting subject; and if the cases were collected which I have overlooked, as well as those which have been altogether omitted, I apprehend that very little more would be gained. I therefore think it safe and reasonable to come to the conclusion, that although these things have happened, they will rarely occur again. I have never, in the great number of broken heads I have had under my care, on many different and grand occasions, actually known the inner table to be separated from the outer, without positive marks of an injury having been inflicted on the bone or pericranium, however slight that injury may have been; and although it is not possible to doubt the fact of fracture of the inner table having occurred, it is very desirable in a practical point of view not to bear it in mind; for if a surgeon should be prepossessed with the idea that the inner table might be so readily fractured, and separated from the diploe placed between it and the outer table, and thus cause irritation or pressure on the brain, few persons who had received a knock on the head, followed by any serious symptoms, without fracture or depression, would escape the trephine, and the worst practie would be again established. An operation should never, then, be performed under the expectation that such an accident may have happened, unless it is apparently required by the urgency of the symptoms indicating compression or irritation of the brain, which cannot be relieved by other means.

I by no means intend to imply by these remarks that a blow on the head will not frequently detach the dura mater from the inner table by rupturing its vessels, and thus give rise to compression or irritation of the brain from the effusion of blood or the formation of matter, or that the inner table may not from the same cause become diseased, and be the cause of ulterior mischief; but these are altogether different states of injury to that which I have just noticed, and require special consideration.

It is not generally known, we believe, that a sabre wound that penetrates the scull does not produce a simple incised wound of the bone, but as has been shown by Mr. Guthrie (and we believe for the first time), is uniformly attended with a fracture or a splintering, with depression of the inner plate, and requires the application of the trephine. The following passage illustrates the practice to be pursued in such cases:—

A British soldier received a wound at the affair of El Boden, in front of Ciudad Rodrigo, from a sword on the top of the head, and accompanied me to Sabugal, on the retreat of the army. The bone was apparently only cut through, yet the inner table was depressed, and felt rugged when examined with the probe. The symptoms of inflammation increasing on the fourth day, and not being relieved by copious bleeding, I removed a central portion of the cut bone by one large crown of the trephine, and took away several small pieces which were sticking into the dura mater, after which all the symptoms gradually disappeared.

As these cases at first are often attended with no serious or alarming consequences, but are almost uniformly *fatal* if not relieved by operation, a question arises, when should the operation be performed? The question is one of some difficulty. The general rule of practice is not to operate till some symptom of danger arise; and this rule of practice is, we think, without exception. The practice of operating to *prevent* bad consequences, though sanctioned by the high authority of Pott, is now justly exploded. If our author in the following passage wishes to inculcate a revival of the practice of Pott we would feel it our duty to oppose and denounce the practice in the most positive manner; but as we know from the whole tenour of the work that this cannot be the meaning of our author, we are bound to apply the practice to cases of a particular kind; and we think he has expressed himself too strongly and unguardedly even regarding these; for though it is a very proper thing to remove pieces of bone that are sticking in the membranes of the brain, yet, as a general rule, it is also a very improper thing to trepan when no symptoms exist demanding the operation. We must take for granted then, that in the following passage the symptoms are supposed to be *urgent*, and the practice inculcated will then be sound and unexceptionable:—

It appears to me that too much stress is laid upon a difference which is supposed to exist in the danger of trephining a man on the first or on the seventh day after an accident, and that an error may be committed in believing that the trephine is a more dangerous instrument on the first day than on the seventh. The question here is not whether the man is to be trephined or not? but which will be the best and safest day or time to do the operation? I do not hesitate to say the first day. I believe the violence to be greater when done on parts already in a state of inflammation than when they are sound. I am quite satisfied, that when the inner table is sticking through the membrane, and into the brain itself, the individual will in most cases ultimately die miserably of the accident, if not relieved by art; and that it is less safe to let him designedly run the certain risk of cerebral irritation, which, when once excited, is often indomitable, than to remove the cause, and so endeavour to *prevent* the evil.

The remaining part of the work is allotted to injuries of the scalp, and to the consequences of such injuries, as erysipelas and suppurations externally or internally to the cranium. Collections of pus *under* the cranium constitute some of the most important and difficult cases in surgery. The difficulty, however, is not regarding the principles of treatment, for those have long been established, and may be said to consist in preventing, if possible, by suitable anti-phlogistic means, the occurrence of such mischief, and when pus does form, of evacuating it without delay. The difficulty exists

when there is no guide externally to the seat of the evil; shall we, then, perforate the scull at random, or shall we not perforate at all? The question is not mooted by our author, yet it is a very important one, and which engaged much of the attention of the older surgeons. Dease and Pott inculcate the evacuation of *the pus* by every means in our power, and we think the practice commendable. The lodgment of pus within the cranium is incompatible with life. To refrain from operating is to consign the patient to inevitable destruction; the operation, therefore, can do no harm, and may be productive of incalculable benefit. The same reasoning applies to the removal of matter from under the dura mater, by puncturing or incising that membrane, or even, if need be, of plunging the lancet into the brain. The following cases, detailed by our author himself, will show the value of this line of practice:—

Absalom Lorimer, of the 42nd regiment, was wounded by a musket-ball on the 10th of April, 1814, at the battle of Toulouse, which carried away a small portion of the scalp, just above the right temple, fracturing the bone slightly, but without any depression. No symptoms occurred demanding more than the ordinary attention for the first fortnight, during which period he had been bled once, purged, and kept on low diet. On the 25th he complained of pain in his head around the wound, and shooting to the back part; pulse 60, pupils dilated. An incision being made to the bone, the pericranium was found detached, the bone fractured, but without any obvious depression. V. S. ad ℥xx. calomel and colocynth; and, as the pain continued, the bleeding was repeated in the evening.—26th. Pain in the head greatly relieved; pulse 60; bowels torpid. Ten ounces of blood were taken from the temporal artery, the calomel and colocynth, salts and senna were repeated. On the morning of the 29th, the symptoms of compression having increased, the trephine was had recourse to, and the fractured portion of bone was removed; a layer of coagulated blood was found on the dura mater, which puffed up into the opening. In the evening he became convulsed, the pulse intermitted, and he died. On examination, a large abscess was found on the right hemisphere of the brain, having the ventricle for its base, with some matter on the surface of the brain, and between the dura mater and the bone at the base of the cranium.

On the morning of the day that I performed the above operation, I had done another of the same kind at the Hospital des Minimes; the dura mater rose up into the opening made by the removal of the circular piece of bone by the trephine, in a similar manner, and without pulsation; and on my puncturing it a considerable quantity of pus oozed out. The opening was enlarged, and the flow of matter was daily encouraged, until it gradually diminished, and ceased with the formation of granulations and the drawing in and cicatrization of the part.

After fractures with depression, or the operation of trepan, *hernia cerebri* sometimes occurs; and our author has made some excellent observations both on the pathology and treatment of such affections. It is proper to remember, that inflammation of the brain uniformly accompanies such protrusions; and that the antiphlogistic treatment constitutes the basis of every plan of cure, whether the protrusion should eventually require to be sliced away, as in cases in which blood is incorporated with cerebral matter: or graduated pressure be adopted, as in cases of simple cerebral protrusion.

We have thus given a full and impartial review of the work before us. The chief defect in the work is a want of arrangement: for a book of reference this is a serious evil. We would recommend the learned author, in the next edition, to divide the book into chapters, and furnish a table of contents; this would render the volume much more useful. The space we have allotted to this notice shows the high opinion we entertain of the work. We hope the author will continue his career of activity and usefulness. He has already done the profession and public some good service by his literary labours; and we shall be happy to meet our author soon again in the field of surgery, in the cultivation of which he has been already so eminently useful.

On Nervous Diseases, Originating from Morbid Derangement of the Liver, Stomach, &c., occasioning Low Spirits, Indigestion, and Gout; also, on Disorders produced by Tropical Climates, &c. By GEORGE ROBERT ROWE, M.D., F.S.A., Mem. Roy. Coll. of Phy. and of the Roy. Coll. of Surg. of London, &c. &c. &c. Fifth Edition.—John Churchill.

IT seems almost a work of supererogation to criticise a treatise which has now reached its *fifth* edition, because this very fact proves that it has been favourably received, and that it requires neither the announcement of the critic, nor the panegyric of the friend, to recommend it to public notice, or to secure it private patronage. But it is, almost as much, our duty to point out, in our journal, and record in our pages the progression of works, which, like this, are firmly established with the public, as the appearance of those which are candidates for the same honour.

We have no hesitation in placing this work among the first ranks of those which have succeeded, for very few preceded it, notwithstanding the *Times*, in a very flattering notice, in May last, when speaking of the *fourth* edition, stated that it contained "much that had been already laid before the public by Dr. W. Combe, and other medical writers,"—whereas the *first* edition of the volume was published in 1820, a period when neither Dr. Combe, nor any other medical writer of the present day, had touched upon the subject. Passing over this blunder of the *Times*, and proceeding to the author himself, we find his style at once simple in detail, yet opulent in fact; concise, and yet leaving little to desire; practical, yet possessing the charms of theoretical disquisition. The first chapter, devoted to "Low Spirits," and the Influence of Sympathy, is thus cumulatively composed:—

When the stomach is disordered, languor, debility, restlessness, and impatience are the consequence, and the great sympathy between that organ and the skin is manifested by eating of shell fish, which will, in some peculiar habits, produce a violent eruption, and the external application of cold in fevers occasionally excites vomiting; also, worms lodging in the coats of the stomach, by their irritating powers on its nervous sensibility, cause convulsions in the whole frame. Nothing makes more surprizing changes in the body than the affections of the mind, and when it is considered that the action of the heart is greatly accelerated, or nervous energy preternaturally diffused by fits of anger, the unity of action between the arterial and nervous systems is daily demonstrated. It is but reasonable, therefore, to suppose, when the circulation is languid, that universal debility will be the result, and the contrary when stimulated.—pp. 18 and 19.

These remarks are corroborated by the experiments of Dr. Beaumont on the stomach of Alexis St. Martin. They proved that sudden emotions of mind, as well as febrile action, occasion an almost immediate change in the vascular appearance of the mucous lining of the stomach, and in the secretion and sensible properties of the gastric juice. When St. Martin suffered from a febrile attack, Dr. Beaumont found that secretion of the stomach was suspended, and that if any food were introduced at that period, it remained undigested for four and twenty hours.

The symptoms of hypochondriasis, vapours, or, as Dr. Rowe calls this form of indigestion,—in which, *we* believe, the brain plays a very principal part—Low Spirits, are exceedingly well described, and must strike the invalid as the fruit of observation and extensive practice. We give them verbatim:—

Want of appetite, indigestion, debility, faintness, and sense of great sinking and fulness of the stomach, flatulence in the intestines, acid eructations of wind, nausea and frequent vomiting of dark fetid liquor, pain and spasms extending across the epigastric region, great depression of spirits, impatience and anxiety, clay-coloured evacuations from the bowels, sometimes in a relaxed, at others in a costive state, hæmorrhoids or piles and frequent discharges of blood, flushings of heat and cold shiverings all over the body, pains in the back and shoulders, spasmodic affections of the muscles, tremblingly alive to a sense of danger, restlessness and want of sleep, sudden startings on the slightest unexpected noise, frequent sighing, a sense of great oppression about the region of the heart, with violent palpitations, the skin is dry and constricted, tongue furred and an unpleasant taste in the mouth, fœtor of the breath, tremors more particularly when the stomach is empty, with frequent yawning, pains in the head, with frightful dreams and hallucinations, pulse irregular and intermittent, giddiness and confused noise in the ears, vision frequently obstructed and imperfect, impaired memory, wandering and unconnected thoughts, want of resolution, considerable difficulty in being roused to either mental or corporeal exertion, former occupations which were regarded with pleasure and satisfaction now become tedious and irksome, and many other symptoms which it would be tedious here to enumerate.—pp. 24 and 25.

The rules laid down for diet, exercise, and amusements, are judicious and scientific. We regret we cannot make room for them, but the following extract will be found highly interesting, not only to the invalid but the student:—

The principal and most powerful causes of indigestion, and all those distressing maladies resulting from it, are the present fashionable modes of intemperance, and the almost total negligence of taking air and exercise. *Homini cibus utilissimus simplex; acervatio ciborum pestifera et condimenta perniciosa, multos morbos multa fercula ferunt.** When the prevailing revolutions of the day to night, and the night to day, are considered, independent of the great indulgence in luxurious habits of living, and the sudden transitions from a temperature equal to that of a tropical climate, to one under the frigid zone,—by rushing from a crowded theatre or ball-room into a dense or frosty atmosphere,—it is but reasonable to conclude, that those organs, whose healthy actions are so dependent on the regularity and temperament of the body, must ultimately become the objects of attack. Hence, we daily witness the robust appearance of the labouring peasantry compared with the pallid hue of the artist and mechanic, who is shut up in a heated room, frequently respiring the same air which has passed through his lungs: the one will be seen enjoying his meals with the greatest avidity, while the other's appetite becomes vitiated, and he loathes the sight of food.—pp. 87 and 88.

From the copious extracts which we have given, it will naturally be inferred that we entertain a very high opinion of the utility and value of this work: we therefore recommend it warmly to our readers, as a practical treatise from which much is to be gained, and a scientific dissertation from which a great deal is to be learned. Before concluding, we shall offer one remark, which, however, is philological, or rather literary—yet, as a matter of curious information, it may not be altogether unacceptable. In quoting the line at page 97,

Incidit in Scyllam qui vult vitare Charybdim.

Dr Rowe, in common with almost every author we have ever opened, who has introduced this

---

* Pliny, Lib. 11, c. 52.

quotation, has given it to Virgil. It is strange that a poet whom we have all read, and at that period of our lives, too, when memory is most tenacious, should be so often misquoted. But such is error—a fact once mis-quoted, mis-stated, or mis-represented, how difficult to set it right again! The line is not in Virgil, but in the "Alexandries" of Philip Gaultier, a French poet of the 13th century, whose works were printed at Lyons, in 1558. It forms a part of the passage where the poet addresses Darius, when, flying from Alexander, he falls into the power of Bessus,—

Incidis in Scyllam cupiens vitare Charybdim.

This blunder is unimportant in a work like the present, but it is worth contradiction, if merely from its universality.

TO CORRESPONDENTS.

Mr. Cooke *can have the numbers if he will name them. Their safe transmission through the post will be doubtful.*

J. W. B. *of Houghton le Spring, sends us this mournful case for advice. We give the sufferer the benefit of its insertion.*

"Sir,—For about six years I have suffered from an affliction, which has nearly exhausted the desire to live, and quite drained my purse. I have had the best medical attendance that I could procure, and all to no purpose. I write to you as a dernier resort, *to ask if you, or any of your contributors, can and will give me the information through your paper, (which I now regularly see), how I might likely get some relief from my misery. The disease is that of sore legs. They at first ulcerated between the calf and ancle, and they now are one continuous sore from ancle to knee. The discharge is of a thin gummy nature, and has a fœtid smell, and proceeds as it were from a number of pin-holes all over the leg. I am now quite free from ulcers beneath the skin; the skin has a reddish livid hue, and seems as if inflamed. My general health otherwise is quite good; I have a good appetite and am quite regular in my bowels. My present treatment is washing the legs in warm water every morning, and applying simple ointments, and bandages rather tight. I take now no medicines."*—J. W. B.

If our Correspondent gives us his name in confidence, we will forward to him the replies elicited by his case. We cannot engage to publish them.

Dr. Turnbull *tells us that we were in error in supposing him to have abandoned the use of hydrocyanic acid for bisulphuret of carbon, in certain diseases of the eye, and thus explains himself:—*

"One reason why I did not rest satisfied with the great effects produced by the hydrocyanic acid, was, that its action, like that of all other medicines, decreased in power by continued application, thereby rendering it necessary to have occasional recourse to other medicines, in order to ensure a more speedy recovery. Another reason was, the reluctance of many individuals to submit the eye to the action of so potent a medicine."

We ought we presume then to have said partially abandoned. *The Doctor is quite right in supposing that intentionally we would do neither him nor any one injustice.*

Antimonopolist, *who came from Tring (about* 10 *miles) in his praiseworthy anxiety of serving the good cause of Medical Reform, sends us a long letter, declaratory of the disappointment he suffered from the proceedings of the British Medical Association. He tells us he considers our abstract a very good summary of what took place. He is of opinion that the resolutions were not of a practical character—that they were of almost a worthless character—while the objects they dwelt on were chimerical, and after a few strictures on the objectionable nomenclature Dr. Hall would introduce into the profession, and the novel pronunciation Dr. Grant would introduce into common use (ex. grat. "coporations" for "corporations") dilates in profuse panegyric on the merits of Dr. Lynch's oratory, which, in the excess of his admiration, he declares to be worth the supper money. He concludes thus:—"I think that a general meeting of the whole profession should be called, some mode of action should be adopted, for which all might contend. Drs. Webster, Lynch, and Granville, might represent the association—the counties might send delegates. Tring and Aylesbury we are assured would do their duty, and would not fail to operate on their country members." This would be something like the sort of* action *wanted, and we should be not a little pleased to see it exhibited. In answer to one remark of our Correspondent, we must remind him that a year ago when we enlarged on the mismanagement of what should be a useful association, we recommended strongly that it should be joined generally, in the hope that an influx of new members while increasing the strength of the union, would lead to some improvements in the Government. That recommendation was not we have reason to know without its effect, though we regret to say the effect produced no general improvement. For some time, as if the society deprecated publicity and support, there existed a rule that no reports of the Council's doings should be published, except in one medical journal; and when subsequently, by a special vote, the* "Medical Times," *was added as a second, the secretary took the liberty of omitting to send the voted documents, and thus the only one good thing done by the society in the year was vetoed by the society's secretary! What association could stand against such mis-rule from within as this!*

Walter C.—Mr. H. W.—A Subscriber, Exeter.—"A Humbugged Member"—L. L.—A. B.—A Constant Reader, Edinburgh—*under consideration.*

The Case of Gun-shot Wound, by Mr. Smith, as also several other Correspondents, next week.

A Subscriber.—*The College of Surgeons does not "possess the power of dismissing from their body a member who has avowedly identified himself with, and practises on his patients according to the Homœpathic doctrines." Nor does the Apothecaries Company possess any such power over licentiates.*

Mr. Atkinson.—*We endeavour to avoid* all *epistolary controversies: one on the subject named, would be* (we *think) most of all imprudent.*

R. D. H. *is thanked: his note will appear next week. Other answers next week.*

Our Subscribers are respectfully reminded of our late circular. *Several of our Irish friends are thanked for their immediate response: and we can hardly do better than offer the promptitude with which they* ever *answer to the call of honour, as an example to some gentlemen who live nearer our office, without being a bit nearer a settlement in our ledger.*—Verbum Sapienti.

NOTICE.

ON THE 1st OF DECEMBER NEXT, WILL BE PUBLISHED, AS AN APPENDIX TO OUR ORDINARY NUMBER, A **MEDICAL ALMANAC**, REPLETE WITH MATTER THE MOST VALUABLE AND INTERESTING FOR THE MEDICAL PROFESSION.—IT WILL CONSIST OF 72 QUARTO COLUMNS.—PRICE 4*d*. PLAIN, 5*d*. STAMPED.

THE MEDICAL TIMES.

SATURDAY, NOVEMBER 19, 1842.

Aude aliquid brevibus Gyaris, et carcere dignum,
Si vis esse aliquis. PROBITAS laudatur, et alget.
Criminibus debent hortos, praetoria, mensas,
Argentum vetus, et stantem extra pocula caprum.

WE notice with a pity for the author truly painful, and a height of disgust which almost makes us ashamed of belonging to a Profession contaminated by his membership, the commencement of an infamous attempt to prop up the sunken fortunes of a doomed journal by a course of hebdomadal calumnies, personal and professional, on every distinguished Member of the British Faculty. The dull writer—the vulgar *bravo* of a still more vulgar master—is to occupy, it would appear, the pages of a *professedly* scientific journal with the very opposite view to that of extending the boundaries of human knowledge, or enlarging the benign influence of the human sympathies: his one, sole object is to be, to hack the character and mutilate the peace of all above him, by debasing with slander all those below them. High science being the sure provocative of his Vandal envy, its possessor's private character is to be ripped up, not for the purposes of truth, but, to serve the misrepresentions of malevolence: unsound opinions, absurd reasonings, immoral expressions and principles, are to be freely attributed to him; all that vulgar impudence and daring unprincipledness can allege, to rob him of that reputation, which is at once the honour of his profession and the subsistence of himself and family, is to be unscrupulously charged on him;—nothing, in truth, within the range of the vile Scribe's imbecile powers is to be withheld, however ungentlemanly, dishonourable, unmanly, or base, which may have the remotest tendency to excite ridicule, contempt, ignominy, and hate, for all who have dared by their genius or labours to advance the noble interests of science, or cast a halo of glory over our much abused Profession!

And why is calumny thus to be poured out like water? And why are the peaceful, the ennobling studies of science and humanity's best friends to be broken in upon by this dæmoniacal exhibition of malevolence? Vice herself, accustomed to services rendered at a cheap rate, revolts against the reason. It is a hope—an improbable, a forlorn hope—to prolong the days of a death-smitten journal. A declining income was in question, and in a remote chance of partially saving it, the demoralized speculator goes merchandizing in characters! In coolly laying down his plan, the ruined reputation, the murdered peace of a medical brother is counted as so much possible addition to the year's receipts! Oh, virtuous projector! oh, most wise speculator!

And what think our brethren of this cool opinion, that the ready way to secure their favour as men, is to weaken those amiable ties of respect and amity which when strongest are, alas, but too feeble, to darken that human nature which, when brightest, is always, alas, too clouded, to multiply those heart-burnings which when least nurtured are always, alas, too numerous—that the sure way to win their support as practitioners is to fan the flames of that personal envy and uncharitableness, which already form the Faculty's Hell, to drag down into the mire the few men whose elevation reflects dignity on their brethren—to strip, in fine, our Profession of public respect and confidence, and, discrowning it of its usefulness, its honour, its purity, to degrade its members into mere conceited bullies and unlearned slander-mongers? Are our brethren flattered with this *honouring* notion? We think we know their answer. The very touch of a journal conducted on such detestable principles will be felt to be contamination; directly or indirectly to support the moral pest, will be to

register one's name as the wicked *fautor* of a mercenary slanderer; to be its reader and a denizen of good society will be considered a moral impossibility. The demented calumniator never made a falser step—never more miscalculated. He has made bad worse. The moribund *Lancet* following in the same wake with those receptacles of filthy slander—the Paul Pry and Penny Satirist—must inevitably meet the same fate. Increasing enlightenment—a changed, a purer taste, has irrevocably pronounced the death warrant of all such public culprits.

Those of our readers who are accustomed to us, know, that the condemnation we have thus strongly expressed, originates in no prudishiness of overwrought morality,—no silly affectation of transcendental respectability. There *is* a bold and manly criticism of the words, the deeds, the public character of our public men; there *is* a refined analysis of their powers — a searching scrutiny into their merits. *This* is at once the privilege and duty of journalists, which we have not only claimed for all others, but have exercised with no timid freedom ourselves. But we see an immeasurable distance—the distance between honest virtue and mercenary vice—between this and our contemporary's awkwardly elaborated system of slander—a system which endeavours to make the sensible appear fatuous, the worthy contemptible, the learned ignorant, the experienced unwise, the good vicious, by the false, the deliberately false, attribution of sentiments to them which they never would and never could utter. As Christians,—as gentlemen,—as men, we feel it a primary duty to brand so low and mercenary a criminal with the name that alone tells his vices, and to hold up to public desecration a course which, if attended with the success the sordid speculator in the ruin of characters so foolishly expects, would make our Profession, what a foreign savant, who formed his opinion of us from the pages of the *Lancet* in its earlier days, once thought us—"a heap of calumniators topped by a few calumniated."

Mr. Erasmus Wilson, whom a hard fate has compelled to sell his abundant leisure to a harder master, promised in one of his recent and better moments, to follow Mr. Lane, and withdraw from the contaminating connection if this threatened career of calumny and fabrication, were recommenced. It *has* recommenced; his brother surgeons and practitioners, who recognize no gentleman in one continuing in *his* position, have not yet heard of his retirement.

A parallel suggests itself to us in the incidents marking the rise and fall of the *Lancet*. As Napoleon, when his downfall was imminent, sought succour by reverting to the early arts which earned him his elevation, so the debased and vulgar Wakley, presenting *one* point of resemblance to the fallen hero, returns for aid, at the feeling of loss, to the old practices which purchased him his success. But the early arts of Napoleon were the noble arts of a generous and ambitious statesman: the early practices of Wakley, the incendiary blackguardisms of a mercantile assassin of character!

Scribendi recte sapere est et principium et fons

In the last number of the Medical Times we expressed a high opinion of Mr. Grainger's contribution to the cause of Medical Reform. We now proceed to discharge the promise we then made, of early laying its principal contents before our readers.

The liberation of the profession from the *trading druggists*, who, by a strange anomaly, are now at its *head*, has always been a main object of Medical Reform. Perhaps no country in the world but our own, presents a legal system in which men who, by their education, attainments, and duties, occupy the sphere of gentlemen, are compelled, in order to enjoy the liberty of exercising their professional competency, to connect themselves as inferiors and subordinates to a city guild composed of tradesmen—respectable, it is true,—but still tradesmen. On this subject Mr. Grainger thus expresses himself:

> I freely admit, what indeed has been universally conceded, that the Apothecaries' Company have made most successful efforts to promote this essential object, and that to the successive extension of their *curriculum* very large part of the advance made by the profession at large, in scientific knowledge, is attributable. As it is through the medium of this body that the great majority of practitioners enter the profession, its character and operations become objects of moment. Without indulging in any personal allusions, it is necessary to point out distinctly that neither the constitution of the examining board, nor the powers under which it acts, are calculated to realise what the spirit of the age demands. It is not becoming that the most important affair connected with a liberal profession should be entrusted to a trading company, nor that the only act of Parliament regulating medical education should compel a man of science to commence his career as if he were entering upon a mere handicraft occupation, by a lengthened apprenticeship. The clause enforcing this apprenticeship of five years has been, in the estimation of those best qualified to form an opinion, the great barrier to the scientific education of the medical student in this country, and until it is entirely effaced from the statute book, all attempts to effect improvement in this way will be in vain. It is, for instance, mainly owing to this clause that young men enter the profession at so early an age that there is not sufficient time for that preliminary education, the want of which has been so generally lamented. It is true, indeed, that the Court of Examiners, perceiving the evils of their own regulations, have recommended the student to devote a part of the period allotted to the apprenticeship, to the attendance on lectures, &c.; but to my certain knowledge, in a great number of instances, this advice, from ignorance or other causes, is not followed. Repeated cases have been stated to me of young men having been occupied during the whole five years in the mere business of dispensing.

This is a most intolerable grievance, a vast injury to the interests of science and the well being of society. If anywhere time should not be mispent, it is in the medical studies; if by any one abilities should not be wasted, it is by the medical student. In trades, or other professions, the forfeit of ignorance or incompetency is money; in medicine, LIVES! Mr. Grainger continues:

> The apprenticeship clause is not only objectionable, for the reasons just stated, but it inflicts, as it appears to me, another and a more serious injustice upon the student, from which, it is to be hoped, he will be speedily relieved. The Court of Examiners by extending the period of attendance upon lectures and hospital practice to three winters and two summers, without previously obtaining from the legislature a repeal of the apprenticeship clause, have virtually, in a great number of instances, compelled the pupil to be engaged eight years in the profession before he could obtain the licence to practice. Now, when it is considered that four years is the longest period of study required in the most celebrated universities in Europe preparatory to taking the degree of doctor of medicine, the injustice of compelling the English student to devote twice that time in order to become a mere licentiate of a City company, is rendered conspicuous. When such a demand is made on the time and purse of a student, he has a just claim to the distinction which a degree would confer; and that such distinctions are eagerly sought after, is proved by the large number of young men who seek to acquire the diploma of the University of London. Last year as many as eighty students presented themselves for examination, and as the degree confers no legal title as to practice, it is clear, what my individual experience confirms, that the main incucement was the honour of belonging to a liberal and learned body. I know of no circumstance more honourable to our profession than this fact, which in itself speaks volumes as to the want of a Faculty of Medicine in this metropolis. As it is, there is at present every thing to discourage the noble aspirations after academic honours which clearly actuate a large number of the rising members of our profession; so that instead of finding the fostering care of a liberal institution to cheer him onward in the toilsome path by which alone scientific distinction is to be attained, *the English student must make his way under every discouragement, and not only have his attention distracted by preparing for two or three separate examinations, but must incur an extra payment, which always presses hard on his limited resources, and but too often acts as an insurmountable barrier to the attainment of the honourable and legitimate object of his ambition.*

Mr. Grainger adds, that this portion of the question of Medical Reform has not had sufficient attention paid to it. We entirely believe this, and the reason is this:—that medical men naturally think more of the grievances actually pressing on them, than those they have left behind them. The evils here exposed, though—thanks to the Medical Times—not for the first time, are the evils of medical students; and as these seem little disposed to ask for a remedy, we must await one, we suppose, in the wisdom of some clear-sighted and bold statesman, who will one day, it is to be hoped, place the whole polity of medicine on a basis of just, enlightened, and enlarged principles.

On the principles of Medical Government, which now obtain we have the following judicious remarks:—

> The experience of the few last years has shown that a very general and growing feeling of dissatisfaction exists in the profession respecting the manner in which the Colleges of Physicians and Surgeons have exercised their powers; and when we recollect that the great body of members have been and continue to be, pertinaciously excluded from all participation, both in the honours of the profession and the management of its affairs, it requires but little insight into the springs of human action to perceive that so long as a system which is thus repugnant to every feeling of self-respect is persisted in, there never can be, and, what is more,

there never ought to be, a cessation from every fair and legitimate means of opposition. Some persons may indeed consider these questions as unworthy the notice of scientific men; but we do not find that in other professions there is any indifference to such matters; the titles, dignities, and power, attached to them, being considered as fair and honourable objects of ambition.

In the case of the College of Surgeons there is an additional and most just cause of complaint, that the ground of disqualification is made to infer a positive inferiority on the part of those excluded; the vast majority of English practitioners being represented to the public as forming a lower grade of the profession. In the scheme of reform lately brought forward by the Council of the College of Surgeons it is understood that the same principle, which has hitherto been acted on by that body, was still recognized. Assuming this to be the case, it may be desirable to pause for a moment, and inquire what that principle is, which is thus so tenaciously retained. It is, as far as I understand, this—that the practice of medicine (as contra-distinguished from that of surgery) or of midwifery, disqualifies the individual so practising from all participation, even the most insignificant, in the honours or management of the affairs of the College. Now, gentlemen, I do not hesitate to say that no proposition could be conceived more injurious to the real interest of surgical science, than this attempt to perpetuate that distinction between medicine and surgery, which the unanimous voice of the profession has declared to be equally detrimental to the interests of both.

On the Divisions in Medicine Mr. Grainger observes:

It is the highest glory of modern surgery, that, by medical treatment, the necessity of operations has been obviated in a vast number of cases in which formerly the only hope of relief was in a painful mutilation; and all those who are anxious to alleviate the sufferings of our race would assuredly exert their power to encourage the practitioner of surgery to persevere in the same direction; least of all would they wish to see a retrograde movement, sanctioned by the authorities that be, towards the principles of those dark ages when medicine and surgery were divided between the monks and their barbers. At a time when all classes of medical men are, from conviction, agreed that there should be an uniform education for the surgeon and the physician, it is apparent that a plan which would disfranchise the great body of practitioners, and place the elective power in the hands of about two hundred of what are called pure surgeons, would only tend to perpetuate those dissensions in the profession, which are, I believe, entirely attributable to misgovernment.

In the next remark we quote, our agreement is not quite so complete. We, of course, no more hope to suppress all quackery by Act of Parliament, than all thievery; but we think much more might be done than Mr. Grainger imagines. We gave our plan in Vol. 6, which is the one (expanded and more complete) which the essayist's "esteemed friend" appears to support. If Dr. Hodgkin claims priority in advancing the scheme, we should be happy to hear his reasons, and give him the credit he deserves. But to the quotation:

To expect, by any legislative enactment, entirely to suppress quackery, is, I believe, a vain anticipation; so long as there are knaves and fools in the world, will there be professions of cure by ignorant pretenders. Indeed, when we consider how numerous is still the class of incurable diseases, and the occasional success which attends bold and empirical practice, however much we may lament the fact, we can scarcely be surprised that, when science can hold out no hope of relief the sufferer should sometimes catch at the confident promises of the undaunted quack. Knowing the strong feelings of the profession on this subject, I am diffident as to the correctness of my own judgment, but I certainly agree with those who, like my esteemed friend, Dr. Hodgkin, think that all that can be effected by legal enactment is, in the first place, to prevent the empiric assuming any title which he has not really obtained, so that he shall be compelled to write himself down a quack; and, secondly, he should be punished as for a misdemeanor, whenever his ignorance leads him into injurious mistakes, either of commission or omission. At the present time, however, no attempt whatever seems to be made to repress illegal practice; so that the empiric has a clear field before him. The only body which pretends to interfere is the Apothecaries' Company; and they, of late, appear to have abandoned this part of their duty as a hopeless affair; so that, unless some speedy and effectual change be introduced, there is great reason to fear that we shall lapse again into the state of the profession prior to the Act of 1815.

Mr. Grainger concludes his essay with hints on the necessity of examining druggists on the possibility of preserving the present College, in combination with the institution of One Faculty, and the very great importance of having honorary distinctions, as rewards for high scientific attainments. *We* conclude with the expression of our agreement in his opinions, and our respect for the able and lucid manner in which he has propounded them.

IMPORTATION OF FOREIGN LEECHES INTO ENGLAND.

(For the 'Medical Times.')

It is not generally known, that the leech trade is one of very great extent in this country, and few people are aware from whence this most useful amphibious animal is procured to supply the great demand that is made for it by private patients, as well as the public medical institutions that abound in this metropolis, and throughout Great Britain. In former years Lincolnshire, Yorkshire, and other fenny counties were able to supply the demand; but since the letting of blood by means of the lancet has been partially exchanged for the more efficacious application of the leech to the injured parts, they have been entirely exhausted. At the conclusion of the peace with France, in 1815, several dealers and speculators visited Paris, where they found leeches were easily to be obtained, and at a moderate price. The herbalists and apothecaries who supplied the hospitals, used then to purchase them in small quantities from the conductors of the Diligences coming from Niort, Tours, Orleans, St. Quentin, and other parts of the interior, not as an article of commerce, but only sufficiently to meet their demands. The arrival of Englishmen in the French capital soon excited their suspicions *that money was to be made*; and the conductors were soon on the *qui vive*, that they might make a good market with John Bull. At that time they charged only 10 or 12 francs per thousand, leaving themselves a good profit, as they were able to procure them from the peasantry at 5 or 6 francs. There are various species of leech—the grey or *sangsues grises*, commonly called the speckled; the green, and the black. The first was the only one much in use, being the same species as that formerly caught in England, although the green are equally as good; but the bite being more acute than the speckled, there was a prejudice against them. The black or horse leech was strongly depreciated by medical men as it is considered rather venomous, and sure to cause inflammation: that species is never used either in England or France. The demand from 1815 to 1823 for the London market was, on an average, annually from 8,000,000 to 10,000,000. This increased call soon made the French conductors and dealers turn the leech into an important article of commerce. From 15 francs they gradually rose to 25, 30, 40, 50, 100, and, at last, by their becoming exhausted throughout the whole country, to 200 francs. The Departments that, in 1815, were so abundant in leeches, are now dried up, and the French themselves are obliged to import them from other countries, so as to meet the demand for their own consumption. The great cause of this annihilation of the species, is the over-eagerness of the fishermen to take them, whereby millions were destroyed before they came to a state of puberty, being only *cocons* or spawn. Such has been the profit in the leech business that many of the Paris conductors and petty apothecaries, who had but a few hundred francs, are now independent men, and extensive *propriétaires*, worth £20,000 to £30,000 in funded and landed property. The deficiency in the supply of the leech made the London dealers turn their attention to Hamburgh, where it was found a great traffic in this useful creature was carried on to a very great extent by the Jews: it is, therefore, from that commercial city that the English market is now supplied through the expeditious communication by steam. The Hamburgh merchants procure them at a great expense (as the mortality is very considerable), from Hungary, Poland, Walachia, and the borders of Turkey; but it is expected that the species will, in a few years hence, be entirely exhausted throughout Europe. They are caught in Spain, Portugal, Switzerland, and Italy, but of the green species only, and of so very sickly a constitution, that they will not support the fatigue of a journey to any distance, although they are well packed in wet canvass bags filled with moistened moss. Such is the scarcity of the speckled leech, that it is with difficulty they are now procured; and although there has been for years a prejudice against the green, they are the only species that can now be obtained, and that at an enormous price, being sold in the London market at £8 per thousand, when they formerly could be purchased for 10 and 12s. This high price, added to the scarcity, has caused a most astonishing falling off in the demand, and, on an average, the annual importation from Hamburgh and Paris is not more than 3,000,000 to 4,000,000—as the hospitals and other institutions are only enabled to use them but in cases of the greatest necessity, where bleeding by the lancet would not be so efficacious. Nothing can be of more general use than the leech in a surgical point of view, as it can be applied with the greatest safety to the parts affected, and it is deeply to be lamented that it is so near becoming extinct. The mode of taking the leech used to give employment to thousands of men, women, and children, who entered with their bare legs into the gentle running streams, and disturbing the water with a stick, these blood-suckers soon attached themselves to their bleeding legs, when they were instantly placed into jars. Many attempts have been made to propagate them in *reservoirs*, but without effect, as they will not breed except in marshy grounds and undisturbed running waters. The mortality among the peasantry who are engaged in the leech fishery is very great; not so much from the constant loss of blood, but the effects of exposure in the unhealthy swamps, thereby causing agues and premature death.

EXTRAORDINARY CASE OF CLAIRVOYANCE.

Sir,—The subject of this letter is Madmoiselle Virginie, a somnambulist of Monsieur Ricard's. The first time I saw her was at a *seance* in M. Ricard's house, at which there were about fifty people; I was accompanied by Colonel Kent Murray. During the evening I was put *en rapport* with her, and asked her to describe the person I was then thinking of. I gave no name, nor did I even state the country in which the person was. To my astonishment she began her description with some humour. She gave me the exact portrait of the lady, as well as her character, moral and physical. In points the most minute she was quite correct. Colonel Murray was then put *en rapport* with her, and she did the same thing by him, describing a lady whose name he never mentioned. The picture of the lady's person was perfect, and equally so her character, even to the motions of the body. When we left the room we did so in amazement, at the way we had heard our thoughts read, though, as I shall show bye and bye, there is something more in it than mere

reading of thoughts. It seems as if sometimes she can get *en rapport* through your thoughts, with the persons themselves of whom you think, else how can she tell things of them, of which you yourself are quite ignorant, and this it will appear hereafter, she can do. The next experiments that took place, in which I played a part, and I answer for none others, though I have seen plenty, were when the other day at my request, M. Ricard gave me a private *seance* with Virginie. I took with me Lieutenant Colonel C. and his lady, Major C. S. and his lady, and Captain Robt. Jump. The first experiments we made were as to the power of discovering disease, without any previous knowledge. Mrs. C. S. being an invalid, was first put *en rapport* with her. She described her malady correctly, but did not lay stress enough on the rheumatic pains she suffered from. Colonel C——, whose disease I was quite ignorant of, was then put *en rapport* with her, but she soon enlightened me on the subject. Her description was, he acknowledged correct, though he is no friend to the science, but he cannot deny it, having seen too much of it in his own family. We then left the subject of discovering disease, of which nambulists that they are possessed, to go to "communication of thought," and "view at distance," but we were well convinced by her and other sombefore I proceed with my narrative, I will remark that I cannot discover how far the perception of disease is connected with mere communication of thought. Thus, if I place a sick person *en rapport* with a somnambulist, and the somnambulist discovers the disease, what proof have I, that the somnambulist does more than tell that person their own opinion of what is their own disease. That community of sensation, which I have proved to myself they often possess, may assist them, I have no doubt, but I have as yet no proof they can see the vital organs as they say they can. I have as yet not seen any description or discovery of disease, made or given by a somnambulist, in which they mentioned anything but what they might learn from having community of thought and sensation with the person with whom they are *en rapport*. Still I will deny nothing, though, till I see it often, I am not bound to believe. Let us now return to Madlle. Virginie. Mrs. C. S. being placed *en rapport*, asked her to "see the person she was thinking of." Virginie consented to try and only asked if the person were man or woman; and on being told "a man," she said, after a moment's pause, "I see him. He is in London. Tall; open chested; *beau garcon*; not old, rather young; high forehead; hair long and brown; fine eyes, colour blue, eyes are full; large nose, and large at the bottom; large mouth; smile pleasing; large chin; skin fresh, but not red; fine teeth, but *two of the upper single teeth one on each side spotted*; neither beard, moustache, nor whisker." She said "he once had a few hairs on his chin, but they grew so scanty that he cut them off. He draws. He does not amuse himself. He invents. He has *plans* before him. He communicates his thoughts to an old man, who has much self esteem; is not his true friend, but pretends to be so, to get or learn what he can from him without acknowledging the obligation (*a brain picker.*) The old man has grey hair, and the forehead, or head, slopes backward; he is wrinkled; bad mouth, and a *dirty one*; large cheek bones; neither fat nor thin. The young man is, in fact, quite tired of the old one, for he knows him now. The young one has some family annoyances. He studies much; &c. &c." Mrs. C. S. declared the description perfect, but she did not believe about the spotted teeth,—at least, she had never seen them; and Col. C. S. said his eyes were brown, not blue—though Mrs. C. S. differed with him. About the old man they never heard or knew of such a person.—I then asked who the gentleman was, Virginie had described, for I was quite ignorant. I was told his name, and also that he was an architect, which quite explained the "plans," &c., Virginie talked of. The *seance* ended, and Mrs. C. S. wrote off that evening to the gentleman in London to ask about the teeth, the eyes, and the old man. We have received his answer, and I send you extracts from his letter:—"I believe the description of disposition and character to be true." "Family troubles I *have* at this time requiring much attention. Personally her sketch is correct, save the blue eyes and breadth of chest." "There are two spots on teeth on the upper jaw; and, speaking with a Frenchwoman's notions of hair on the face, she is right in saying I have none, and when I *wished* it would grow, it came too *stingily*." "The history and portrait of the old man is, to the *very letter*, PERFECT"—"it is *singularly* correct"—"I have long known him as a 'brain picker'"—"he is famed for self esteem, and I have thought him more a friend than I do now; in fact, I *am* tired of him: the sketch of his person is exact." "The somnambulist's statement that I indulge rarely in any amusement is very true." It now appears that Mademoiselle Virginie's description was quite correct, except as regards the eyes and breadth of chest. Mrs. C. S. thought they were blue, and Virginie, having communication of thought with her, was of the same opinion,—and after all, I believe, they are grey; as to the chest, although the gentleman may not be remarkable for great breadth of chest, I understand, there is no contraction,—nor is he positively the contrary. Besides, supposing she *had* committed a *great error* in the description of any particular part of him, surely if all the rest be correct, and there be no difficulty from her description to pick him out of a thousand, it could be of no matter whatever. I have confined myself merely to the facts of the case, as all speculation on the subject appears to me absurd, for it can be founded on nothing, till we have collected more facts to fill up the wanting links in the chain of "cause and effect." I will remark that in the case I have just given, there was something more than communication of thought between the somnambulist and the person *en rapport* with her, for Mrs. C. S. knew nothing of the old man, nor of the spotted teeth, nor of his affairs. It seemed as if the somnambulist got *en rapport* with the person thought of through the brain of the person upon whom the somnambulist was *en rapport* with. The beauty of this class of experiments is that there is no room for collusion. Let a sceptic be put *en rapport* with such a somnambulist, and get the description of any person he chooses, naming them only as "the person he thinks of." What can he say?—what room is there to be deceived? It appears to me there is none, and therefore it is true. Those who cannot lay dishonesty or deception to my account, kind and charitable people! say, or pretend to think, that I am the victim of some deception or collusion, got up to deceive me, without any one's getting anything by it. Such an idea is absurd, and I say to them, with Hamlet, "lay not such flattering unction to your soul." It is not our madness, but their prejudice that speaks. It is impossible that we can be deceived as to certain positive facts which we all agree to exist, which we see every day, and about which we have not the least interest to deceive others or ourselves. I will not defend myself and brethren from the charge of roguery, for such an absurd charge has never been made against us *as a body*, even by the most sceptical, nor will I even defend us from the charge of being fools, for even that has never been laid to our door, for it is well known, (I say it without bashfulness) that mesmerisers generally are well read, scientific men, and count now, and have always counted amongst their number, men of the highest talent, intellect, scientific research, and scientific authority. What then is the charge against us? Why the ignorant, the idle in investigation, and such men as those who condemned innoculation as unholy, and Galileo to the inquisition, say, "We are visionaries." Do they know the meaning of the word, or is it in their mouths only a term of abuse? A visionary is he whose belief is founded on his feelings, not on his reason or judgment. A madman *feels* himself a being, and therefore *believes* himself one, for his *feelings* are stronger than his intellectual faculties, and that man is a "visionary." Now, do mesmerisers arrive at their conviction by feeling or reason? Clearly, not by the former; for speak to any mesmeriser of the present day, or read the history of those gone by, and you will see that at first all the feelings were against it, from the *apparent* inefficiency of the cause to produce such effects. I think no person ever believed in mesmerism without having experienced a hard struggle between his feelings (alias, prejudices) and his reason. If his reason be strongest, so as to enable him to judge of the *nature* and weight of evidence, he believes,—and, if the feelings be strongest, he cannot believe. Ask a visionary, why he believes so and so, and he can give you *no chain of evidence, unbroken*, to support his belief, but gives you words and sentences which have no meaning, and which have in them no chain of positive evidence of the thing to be proved. Ask a mesmeriser why he believes, and he will tell you that he sees, daily, certain *positive facts*, which, for want of a better name, he calls "Mesmerism." He offers to prove these facts—and to show them—and *does show them*—yet he is called a "visionary." Were a mesmeriser to stick up a dogma to account for them, and his chain of positive evidence to be incomplete, then he would deserve the name of "visionary;" and that name is well deserved by many French authors. When I use the word, "Mesmerism," I mean only certain facts called "mesmeric," and to which facts, all mesmerisers agree. Doubtless, there are many things given to us as such, by a single author here and there, which are false—or rather, I should say, errors, for where I can discover no gain to be got by deception, it is more probable that the author was mistaken, than that he uttered what he knew to be false. There are plenty of points in mesmerism which I do not believe one word of, and shall not, till they are as much to me of every-day occurrence as the facts I have already attested. Before I conclude, I will be bold enough to give a piece of advice to all mesmerisers. I have had a good deal to do with sceptics, and some very few I have failed to convince. Perhaps, I wound their combativeness by my desire to convince them; so I advise mesmerisers never to shew any anxiety about it.—Secondly, Before ever they allow a sceptic to see any of their experiments, ask them what evidence will convince them? Let them name the experiment, and settle with the mesmeriser, beforehand, how it is to be conducted. This will save great trouble and loss of time, for you will at once discover those who are to be convinced from those who are not.

The following is the sort of conversation I once held with a sceptic:—

Q. Will it convince you that the patient is in an unusual state, if I apply a flame of fire all down his thigh, and he shews no sign of feeling?

A. No. Some men will bear anything.

Q. I deny it; but, if he breathes pure ammonia while you hold his mouth, and see or feel his lungs expand, and he gives no signs of feeling, only increased secretion of water from the eyes, caused by the stimulating, though unfelt, effects of the ammonia on the membrane?

A. Practice, Sir, practice!

Q. Shall I make him deaf, or hear, at a private signal from you?—or, shall I give him any mental order you choose to write and give me, and make him do it?—or, shall he detect a piece of money I have touched, out of a thousand?—or, shall he read with a bandage over his eyes?

A. No, no,—for though you may do it, I can't tell how it's done; it won't prove there was no trick in it, though I can't find it out.

Q. What, then, will convince you?

A. Nothing.

Such men speak the truth—and nothing will convince them.

Your obedient servant,

WM. MACPHERSON ADAMS.

10, Rue Mont-Thabor, Paris.

[We know from good authority, that similar matters occuring in the same locality, are exciting the amazement, and occupying the attention of some of the most illustrious persons in the realm. When we mention that Col. Gurwood, the editor of the duke's dispatches, thoroughly believes (as he says, from recent positive personal evidence) in marvels as startl'ng, we may add as incredible as those above narrated, our readers will surmise some of the high quarters in which mesmerism is likely to be exciting interest. A case of amputation performed during mesmeric sleep, is accepted, and is to be read at the Medico Chirurgical Society, on Tuesday next. We shall notice the paper in our next.—Editor.]

DR. HASTINGS' EXPLANATION.

To the Editor of the 'Medical Times.'

SIR,—I beg to inform you, that I received a similar letter to the one you have published in the MEDICAL TIMES of October 29th, from Mr. Guthrie, as President of the College of Surgeons, and that I read it to the Provincial Medical and Surgical Association at their anniversary meeting, held at Exeter in August last.

I am, SIR,
Your obedient Servant,
CHARLES HASTINGS.

Worcester, Nov. 12th, 1842.

EFFECT OF MATERNAL IMAGINATION ON THE FOETUS.

To the Editor of the 'MEDICAL TIMES.'

SIR, — The influence upon the fœtus, of certain mental emotions occurring in the mother, being a disputed question in physiology, and one of some interest and importance, I have thought that the following cases (for the veracity of which I can vouch) might not be unacceptable to your readers.

About a year ago, one of my dispensary patients shewed me her infant, which presented on the left upper extremity a mere stump, of about two inches in length, beyond the elbow joint, terminated by a puckering of the integuments on which were situated five minute bodies resembling the tips of very small fingers: the child was otherwise perfectly formed. The history of the case is as follows:

Eight months before the birth of the child, the mother, walking with her sister (from whom I have collected the particulars), met with a beggar who, in order to excite compassion, exhibited an amputated stump on his left arm. The woman immediately expressed a sense of disgust and horror, and observed that, if she had been then pregnant, she should expect that her child would be born similiarly maimed. The sequel has proved that she was then pregnant, though she did not apprehend it, and that the fears of the result were too well grounded.

Her sister was present at her labour; and on receiving the infant, and discovering its deformity, experienced a thrill of disgust and sorrow, from which she did not recover until a few days after, when I was called to attend her for abortion, she not having previously suspected that she was pregnant.

A few days ago I was called to attend, in her second labour, an intelligent, respectable young woman, the wife of a plumber residing in Hornsey-road, opposite to the first-mentioned woman. The child, which is otherwise perfect, presents a deformity precisely resembling that above described, with the exception of two imitations of finger ends instead of five, as in the former instance. I have collected the history of this case from the sister-in-law, the husband, and herself. About eight months since, she was subjected to exactly the same causes as those I have related in the other case; she also did not suppose herself to be then pregnant, but expressed the same extreme sense of aversion, and her fear that "if she had been *in the family way*" the infant would be similarly maimed. The sequel of this case like the former, proves her fears to have had their effect.

In both these instances the same dread of the result had been frequently expressed during the period of gestation; and I have reason to think, though, of course, I cannot prove it to my satisfaction, that the same individual vagrant was the cause of alarm to each.

Popular opinion is prone to attribute all monstrosities to the operation of mental influence; and it is not without reason that the medical profession look with distrust upon narratives of this nature; but the cases I have related admit of no other explanation. They are not given without a rigid scrutinizing examination of the histories related by the parties concerned.

It is not because we cannot, scalpel in hand, detect the channel of communication, that the existence of such is disproved—neither is it by ridicule without examination, that the truth will be discovered. On this as on every other undecided point, facts alone, accurately collected, will show on which side truth is to be found; and I conceive, that the cases I have related, do go far to prove—1st, the susceptibility of the fœtus to have its developement interfered with by violent mental emotions taking place in the mother; and, 2dly, that such interference can only occur in the early periods of pregnancy.

The case of abortion I have related merely on account of the relationship between the women, not in illustration of the power of mental emotion to produce miscarriage, as no doubt exists on this point.

I am, SIR,
Your obedient Servant,
W. B. KESTEVEN,
Senior Surgeon of the Holloway and North Islington Dispensary.

Upper Holloway,
Nov. 12th, 1842.

ADDENBROOKE'S HOSPITAL, CAMBRIDGE. —We are requested to announce the election of three surgeons to this hospital—Mr. Lestourgeon, Mr. Hammond, and Mr. G. M. Humphry.

PERISCOPE OF THE WEEK.

TARTAR ON THE TEETH.—M. La Baume ascertained, that washing the teeth with vinegar and a brush, will, in a few days, remove the tartar; thus obviating the necessity for filing or scraping them, which so often injures the enamel. He recommends the use of powdered charcoal and tincture of rhatany afterwards, which effectually (in his opinion) prevents its formation.

AGUE.—Vernal ague is more curable than autumnal. Dr. Seymour has never known quinine fail in curing the former; in the latter he has had resort to arsenic. It is a common mistake, on seeing a foul tongue at the commencement of this disease, to suppose that quinine is inadmissible until the digestive organs are set right. Dr. Seymour says, that the state of the tongue is produced by the fever, and that if you go on purging with the hopes of relief you will render the disease more difficult to cure; he therefore, recommends an emetic, and a purgative afterwards. It is necessary to continue the quinine after the paroxysms are stopped, as sometimes the first dose of aperient medicine will bring back the fit. He alludes to the power of emetics, in altering the periodicity of disease, and draws the attention to the sallow shrunken countenance produced on its continuance, by the determination to internal organs.

CLIMATE. The liver is more prone to disease in the warm than the cold climate, and the lungs in the cold than the warm—for this reason: increased action implies increased determination, and this again disposes to inflammatory action and congestion. But as variety of temperature causes variety in the energies of action in the liver and the lungs respectively, corresponding consequences supervene: and as the lungs are more engaged in *cold* climates, they are also more disposed to disease; while in warmer ones, the liver acting with increased energy, becomes also more susceptible, Phthisis and pneumonia are almost as frequent in hot as in cold climates.

ELECTROTYPE SEALS.—Hold the sealing-wax impression over the mouth of a Florence flask, having a small tube, from which the vapour of spirits of wine is proceeding, by the agency of a lighted candle below; black-lead powder is instantly applied by a camel hair brush; and lastly, a fine point of wood being nicely passed over it, it produces a burnished surface. When the copper seal is removed, touch the back with a soldering iron and pour on your lead or fusible alloy, so as to form a sufficient mass for a seal.

DYSENTERY.—The pathology of dysentery, is inflammation of the colon. There is in general, pain, with a desire to go to stool, and a feeling of a load in the bowels and griping pains; the patient goes to stool and perhaps passes only flatus; afterwards a thin glairy mucus, with, say bile, and afterwards blood, and lymph, as in the cases seen on the Gold Coast of Africa. The membrane sloughs, and there is a thin discharge; the blood is a symptom, not of ulceration, but of inflammation. In ulceration there is a discharge like green tea, and not bloody, except when an artery is involved. In this climate it is almost invariably curable; yielding to purgatives, as long as the patient feels the load in his bowels you may purge according to his strength. Helvetius recommends ipecacuanha, which for some time has been often employed in doses of gr. xv. ad. ℈j. When the inflammation runs very high, colomel must be used, and when it gripes, you must add opium. The ulceration after

dysentery is a slow chronic mortal disease. It is more chronic than the ulceration after fever; because, in the latter, the small intestines are affected, from whose surfaces a greater degree of lacteal absorption takes place, than from that of the larger intestines.

DISEASE OF THE HEART.—Dr. Macleod states that the action of the heart as excited by organic change, is not so perceptible to the patient as when only sympathetically influenced. This remark was made on a case where great pain attending disease of this organ, had been much relieved by the application of morphia ointment to a small blistered surface over the heart.

ŒNEMIA WITH CHLOROSIS.—Dr. Hamilton Roe recommends the use of ol. ricini. and ol. terebinth. *a a* ℥iij., at bed-time; and in most cases it is attended with beneficial results.

TALBOT'S CALOTYPE.—The paper is covered with *iodide of silver*, by washing it successively with nitrate of silver and iodide of potass; afterwards it is washed over with *gallo-nitrate of silver*,* the greater part of which is removed by immersion in water, but enough adheres to render the paper exceedingly sensitive to light. The paper is then dried, and placed in the camera obscura, and the image of a building or other object, is generally obtained in less than a minute. This image, however, is usually quite invisible, and the mode of rendering it visible (which is the most curious part of the calotype process) consists in washing it again with *gallo-nitrate of silver*, and then gently warming it—which generally causes the appearance of the picture, with great force and vivacity, in the space of a minute or less. The theory of the process remains at present unexplained. To fix the picture, it should first be washed with water—then lightly dried with blotting paper—and then washed with a solution of *bromide of potassium*, containing 100 grains of that salt dissolved in eight or ten ounces of water.

INDIAN PREVENTION OF DRY ROT.—At Yaynankhyvin, on the banks of the Irrawaddy, are the celebrated Petroleum Wells, which supply the kingdom of Burmah, and the adjacent countries as far south as Junk-Ceylon, with *lamp oil*. The priests, whose religious works are all written upon the leaf of the talipot-palm (*Corypha umbraculifera*,) smear the surface with this mineral oil, for the double purpose of filling the interstices with a dark matter which shall render the letters visible, and in order to protect them from the attacks of insects, and the ravages of time. I have seen such books of various ages, from fifty to one hundred and fifty years, whose antiquity could be verified without difficulty—their preservation having been attributed solely to the indestructible properties of the Petroleum, in which they had been soaked. Having mentioned these facts, it only remains for me to draw the attention of scientific persons to them, with the view of testing the qualities of Yaynan, as a *preventive to dry rot in timber*. The experiment may be tried without much expense, by saturating some planks with this liquid, and giving them a fair trial with others not so protected. There cannot be the same objection made to this mineral production as there is to arsenic or corrosive sublimate, inasmuch as the Yaynan is not only perfectly innoxious, but has rather an agreeable odour.

* The gallo-nitrate of silver is formed by simply mixing solutions of nitrate of silver, and gallic acid. The operation requires to be executed with great care and precision, but is not difficult in other respects.

MATERNAL IMPRESSIONS ON THE FŒTUS.—*Case* 1: Josephine Minnebol, says M. Guislain, of Gand, was a few weeks advanced in pregnancy; she was in good health; one of her acquaintance came to see her, wearing in her ears earrings, called in Flanders, "petites cloches," (little bells, from their shape.) These jewels caught the affections of Josephine—she admired them, coveted them—gazed upon them with eagerness. Forthwith she was beset with an ardent desire of possessing similar earrings. At the period of her confinement she brought into the world a healthy infant, offering the singular phenomenon of two appendages, an inch in length, and shaped like acorns, hanging by a pendicle to the antitragus of each ear. *Case* 2: M——, an advocate, went with his wife to visit a farmer, in whose house she saw a child having a supernumerary thumb. She had been pregnant a few days. Some time afterwards, she had a dream during the night, in which she saw this same infant, and this same double thumb;—she got up, and uttered a cry of alarm. After this, she was frequently occupied with the idea that her infant would be born deformed. At the eighth month she was delivered of a still-born child, which had a supernumerary thumb. *Case* 3: Dr.——, member of the Medical Society of Ghent, relates the following concerning his wife. His wife, who is not at all superstitious, was pregnant for the fourth time, and in the fourth month of her pregnancy, when, in the winter of 1832, she missed her footing, and fell at full length, first on her knees, and then upon her elbows; this caused her knees, thighs and elbows to be denuded of skin; she was immediately anxious for the fate of her infant, and she frequently made use of the expression to her husband—"Provided that our child does not suffer from it," Being continued at the usual period, she brought into the world a male child, with the knees, thighs and elbows presenting the appearance of torn flesh, denuded of skin. *Case* 4: A woman, in the fifth month of her pregnancy, was engaged in applying a certain number of leeches to the chest of a young man affected with pleurisy. Some time afterwards she brought into the world a healthy child, but presenting on the left side of its chest, marks analogous to leech-bites. It is confidently asserted, that there was a large red ecchymosed patch to be seen close by the former. Twenty-four leeches had been applied, and twenty-four spots were found upon the body of the infant. *Case* 5: A women of Ghent, during the course of her third pregnancy, conceived an insurmountable aversion for a person whom she often saw, and who had her hands bent back at the wrists. She was delivered of an eight months' child, which presented a complete doubling back of the hand upon the fore-arm. M. Guislain also treats of the influence which certain impressions of different animals, perceived by the mother, are able to transmit to the children, as well as of that which the character proper to each kind of animal exercises during incubation, upon the individuals confided to it. He brings forward the fact of a pregnant cat, which struggled with a terrier with crooked fore-legs. A short time afterwards she brought forth a kitten, the fore paws of which were crooked, and remained crooked like those of the terrier. Thus, a hen's egg, sat upon by a magpie, was productive of a game cock, surpassing every other animal of the same kind. Pigeons of a lofty flight covered by heavy birds, were no longer able to quit the earth; and *vice versa*, poulets produced from eggs sat upon by pigeons, have been observed to fly higher, and keep longer on the wing, than other birds of their kind.

CREOSOTE IN PHTHYSIS.—A female, aged 34, under Dr. Fraoz, of Konigsfeld, was affected with tubercular phthysis, and the emaciation of the patient, the colliquative sweats, the aphthæ, fetid expectoration, &c., showed that the disease was already in its last stage. The administration of creosote was then commenced, and after eight grammes of this substance had been given, the improvement obtained was such, that the patient was able to resume her operations. A result no less favorable was obtained with the same medicine administered to a peasant, aged 28, who laboured under phthysis. But, in three other similar cases, its employment was obliged to be abandoned, because under the influence of its action, the cough and all the hæmoptical symptoms were aggravated by it.

REMEDY FOR CERTAIN ALTERATIONS OF THE MILK IN NURSING WOMEN.—A nurse had the milk too clear and scanty; she did not feel it *rise*. The following means, employed by Dr. Chabrely, succeeded in two days correcting the bad quality of the milk, and in greatly increasing the quantity of that secretion:—℞ Magnesia, 10 grammes; powdered orange peel, 3 do.; white sugar, 65 do.; M. and F. S. A. a perfectly homogeneous powder. The nurse took, three times a day, in a cupful of a weak infusion of lime, properly sweetened, a teaspoonful of this mixture. Under the influence of this medicine, her appetite, previously bad, became excellent, and, owing to this circumstance and the direct effect of the medicine, her milk acquired in the space of two or three days all the qualities necessary for affording sufficient nourishment to the child. Madame Armand B. had galactorrhœa for three months, which wasted her. The child fell away. In this case, Dr. Chabrely had recourse to the following medicament:—℞ bicarbonate of soda, 4 grammes; powdered orange peel, 4 do.; white sugar, 80 do.; M. and F. S. A. a perfectly homogeneous powder. Madame Armand B. took, three times a day, a teaspoonful of this mixture in a cupful of a weak infusion of edulcorated *aya-pana*. Under the influence of this medicine, she entirely recovered her appetite, which had left her from the commencement of the galactorrhœa. Two such doses were sufficient to correct the milk and to suspend the incessant flowing. From this time, the lady was enabled to continue to suckle her child, to the great benefit of both, for, in a few days, they acquired their former plumpness.

ANTHRAKOKALI.—Dr. Polya states that he has employed anthrakokali with marked advantage in scrofula, chronic rheumatism, articular rheumatismal tumors, tophaceous arthritic concretions, and hydrarthrosis. Anthrakokali is prepared by mixing in an iron basin 160 parts of powdered coal, with 192 parts of a very concentrated and boiling solution of potassa causticised by lime. When the mixture is made, the vessel is removed from the fire. After removing it from the fire, continue to stir it until it is converted into a homogeneous black powder. He administers three or four times a day the dose of 0·19 grammes, mixed with 0·25 grammes of powdered liquorice. Many Parisian practitioners have tried the employment of this medicine, and among others, Dr. Gibert, who, at the *Hopital Saint Louis*, has prescribed in several cutaneous disorders. Its internal exhibition not having appeared to him very advantageous, this physician employed it under the form of a pommade according to the following formula:—anthrakokali, 1 gramme; lard, 30 do.; M. and F. S. A. a homogeneous pommade. It is applied morning and evening to the

diseased parts. Tried on 24 individuals affected with skin diseases, it cured many of them, and its employment in others was signalized by a manifest amelioration. The action of this medicine appeared resolutive, but less exciting than the preparations of iodine or ammonia.

Paralysis without Loss of Sensation.—W. H. G., Esq., æt. 36.—In 1836, Mr. G. had a phagedenic ulcer of the left leg, which got well after some months; but it again broke out in 1839, when he had also a large chronic ulcer on the posterior pharynx of some duration, but not of a syphilitic character. He had pains in the head, with very costive bowels, during the greater part of the year 1839; in January, 1840, epileptic attacks, with very slow pulse, now supervened; and in the spring following, Mr. G. had spasmodic contractions of the lower limbs, accompanied by a sense of weakness in the back; and latterly he lost the use of his legs, and ultimately the entire control over every muscle situated lower than the neck. During the last twelve months of the patient's life, the whole body was paralysed, excepting the head, neck, and diaphragm, by which breathing was entirely carried on, and not by the muscles of the chest. However, sensation remained, perfectly natural throughout the entire surface of the body; and towards the termination of the disease, the patient's feelings were even more acute than usual, and he could always tell, on the slightest touch of a bystander's finger, the exact spot to which it was applied. Severe spasmodic twitchings of the legs and arms were now more frequently noticed than before, and these were sometimes so violent as almost to throw the patient off his couch. The extremities were often very cold, but occasionally they felt also burning hot, with a sensation of excessive coldness in the epigastrium. The urine was drawn off by the catheter for many months, but latterly it passed involuntarily, as the fæces did likewise. All the symptoms continued unabated in violence to the last, and the patient died in July, 1842; but retaining his intellectual faculties perfect until the last. *Treatment.*—Medicine had very little influence in arresting the disease, although the treatment may have relieved the severity of some of the symptoms. The remedies consisted principally of purgatives, mercury, sarsaparilla, hydriodate of potassa, strichnia, and morphia to procure sleep or allay spasm. Other means were also used, but the treatment which appeared to produce the most benefit was active purging, and the tincture of cantharidis taken as a diuretic; at the same time that a copious discharge was kept up for many months consecutively from two large issues on the nape of the neck. *Autopsy.*—Nothing particular was found in the head, excepting that the arachnoid membrane over the pons varolii adhered to the parietal layer of that tissue, and about two ounces of serum were found in the ventricles; but there was no tumor or change of structure either in the brain or in the cerebellum. The thoracic and abdominal viscera were healthy, with the exception of the bladder, which was much contracted in size, and thickened in its coats, whilst the omentum, and some of the small intestines, adhered to its surface. On opening the spinal canal, the theca, corresponding to the three or four lower cervical vertebræ, was much distended; the arachnoid cavity was filled with lymph, and there were adhesions of the membranes to the chord, which appeared firmer at the anterior than at the posterior portion, and the parts were inseparable. The chord itself was longer than usual at this particular point, felt soft and pulpy to the touch, and on being divided it was found to be in an almost diffluent state, infiltrated with serum, but of a natural colour. For the extent of half an inch above this point the chord exhibited a dusky red colour, but there was no difference observable betwixt the two columns, both being alike softened and discoloured; the parts above and below being perfectly healthy, and of a natural appearance.

External application of Croton Oil.—M. Bouchardat recommends a plaister, used by Chomel at the Hotel Dieu; and which is thus prepared:—Four parts of diachylon plaister are melted at a very gentle heat, and while it is half liquid, one part of croton oil is mixed with it, and the mixture is then spread in a thick layer on calico. Pieces cut from this may be applied to the skin like ordinary sticking-plaister. They quickly produce an active irritation.

Death from the Bite of a Fly.—A tanner, aged 62, living at Saint Maurice, died in consequence of being bitten by a fly. This insect, which was of the most venomous kind, produced a malignant pustule. The face which was the part bitten, first swelled up; and afterwards the whole of the body.

Liquor Taraxaci.—The following is the formula: Dandelion roots, perfectly clean, *dried*, and sliced, 18 ounces. Infuse for 24 hours in a sufficient quantity of cold distilled water to cover them. Press and set aside, that the fecula may subside; decant and heat the clear liquor to 180 deg. F., so as to coagulate the albumen; filter the liquid whilst hot, and evaporate in a drying room, or by means of a current of warm air (a water or steam bath will not succeed so well), until the product shall weigh 14 ounces. To this must be added 4 ounces of rectified spirit. Should the roots not have been perfectly cleansed, the product must be digested with pure animal charcoal. If properly prepared, Liquor Taraxaci resembles in colour pale Sherry, and possesses the acrid taste of the fresh root in an eminent degree. The dose is from one to three fluid drachms.

Hemostatic Water of Monterossi.—M. Gibourt gives in the *Journal de Chimie Medicale*, the formula of the hemostatic or styptic water of Dr. Monterossi of Naples; it is said to be a most successful application in all kinds of hæmorrhage. Mentha piperita; memordica balsamina; teucrium marum; acorus calamus; origanum dictamus; *aa.* 250 grammes; nepeta cataria; mentha pulegium; rosmarinus officinalis; salvia officinalis; Diotis candidissima; eupatoria cannabinum; lanicula europea; achillea millefolium; erythrea centaurium; cupressus sempervirens; rhus coriaria; plantago major et lanceolata; urtica dioica; quercus robur; symphitum officinale; polygonum bistortum; tormentilla erecta; hæmatoxylum campechianum; pix nigra; boletus laricis; *aa.* 1000 grammes. These substances well pulverized are placed in a retort, and sprinkled with water. In the course of 18 hours, a fresh supply of liquid is to be added, and distilled slowly to two thirds of its quantity. The product is to be preserved in closely stoppered bottles. The liquid remaining in the retort may be filtered through paper and evaporated to the consistence of extract. This may either be dissolved in water, or in alcohol; it is, however, less soluble in the latter.

Officinal Iodide of Potassium usually contains, according to Woehler, iodate of potassa and carbonate of potassa, more especially that iodide which is furnished by manufacturers on the large scale. Herzog has shewn the composition of that prepared according to the Pharm. Borr. The salt of the Pharm. Hanov. frequently contains also iodate of potassa, since it is only completely reduced by the long-continued action of sulphuretted hydrogen. The best method is, by decomposing the iodide of iron with carbonate of potassa at a boiling temperature. The difficulty is, to hit the precise point of decomposition, so that neither iodide of iron nor carbonate of potassa may remain in excess. The latter fault is easily amended by the addition of hydriodic acid.

Poisoning by Snails.—A family of peasants living in the commune of Clermont, near Toulouse, fell a sacrifice to poisoning by snails. The physician who attended them, communicated the following details to the *Journal de Toulouse*.—From what I collected concerning the circumstance which preceded the disease, and those which accompanied it, and from the symptoms which I myself witnessed, I had no difficulty in recognising a case of poisoning like those occasioned by narcotico-acrid vegetables, such as belladonna, hyoscyamus, thorn-apple, &c. No doubt remained in my mind as to the cause of this terrible disease, as soon as I knew that the snails eaten had been collected in the bushes, called in French *redout*, but in the patois of the country *roudout* (*Coriaria myrtifolia.*) Every one knows that the leaves and young shoots are a poison to the domestic animals which browse on them, and that they kill them, after causing giddiness and a kind of epileptic attack; but a fact which is not known is, that the flesh of these animals may occasion the greatest danger, and even death itself. Symptoms like those which I have just witnessed, are rare; but it is common to see among our peasants indisposition caused by snails, which comes from their eating them as soon as they are gathered. The example of the ancient Romans should be followed, and these animals should not be brought to table until they have been kept six months or a year, feeding them on bran and wild thyme. This is the way also to make them fatter and more savory.

Mortality in England and Wales.—As compared with the average number of deaths in the same quarter of the four preceding years, 1838, 1839, 1840, and 1841, there is an increase in the past quarter of no fewer than 2,474 deaths, the average for those four years having been 36,595, while the deaths in the past quarter have been, as above stated, 39,069.

ROYAL COLLEGE OF SURGEONS LONDON.

List of gentlemen admitted members on Friday, November 11th, 1842:—

H. A. Arden, G. F. Hewson, H. Vidal, J. H. Kimbell, T. L. Hodson, G. Cole, A Adye, J. P. Bourne, W. Simpson.

MEDICAL NEWS.

Middlesex Hospital. — Mr. Herbert Mayo has resigned the surgeonship to this hospital, and Mr. Shaw the assistant surgeonship. The candidates for Mr. Mayo's place, are Mr. Shaw, Mr. De Morgan, and Mr. Erasmus Wilson.

The Pharmaceutical Society.—That we are not, says the Chemist, by many hundreds, the only parties dissatisfied with and disgusted at the conduct of those entrusted with the management of the Society's affairs, we can amply attest. We have too long conducted our journal to be in the dark in matters relating to

chemists and the conductors of the pharmaceutical farce. We know of the prevalence of the greatest distrust, and let next time of subscription tell how justly we have stated the general feeling. We certainly agree with them that the intended reduced subscription of one guinea per annum will be a much nearer approach to the real value of the transactions than the present tax. Can it be supposed,—is it probable,—that we should first suggest and advise the formation of a society, and then seek to injure or destroy it? Why have we withdrawn our support? Because its affairs are confided to jobbers and ignoramuses.

ADVERTISEMENTS.

London: Printed and Published by JAMES ANGERSTEIN CARFRAE, 49, Essex Street, Strand, in the Parish of St. Clement Danes, Westminster, in the County of Middlesex.—November 19th, 1842.

THE MEDICAL TIMES

A Journal of English and Foreign Medicine and Medical Affairs

No. 166. Vol. VII. LONDON, SATURDAY, NOVEMBER 26, 1842. PRICE FOURPENCE. Stamped Edition, 5d.

For the convenience of Subscribers in remote places, the Weekly Numbers are re-issued in Monthly Parts, stitched in a Wrapper, and forwarded with the Magazines. Orders for the Stamped Edition (10s. 10d. per Half-year, Post free in advance) are received by any Bookseller or Newsman, or may be directed to J. A. Carfrae, Esq., at the Medical Times Office, (late Lancet Office), London.

SUMMARY.

COURSE OF LECTURES ON THE THEORY AND PRACTICE OF MEDICINE.

Delivered by C. J. B. WILLIAMS, M.D., F.R.S., Professor of the Practice of Medicine, and of Clinical Medicine, at University College.

Gentlemen,—The divisions of inflammation that I mentioned at the conclusion of my last lecture are entirely arbitrary. It is, however, useful to have some general terms by which to characterize the leading features of a disease, and as the terms acute or sthenic, and sub-acute or asthenic, indicate pretty clearly the nature of an inflammation, it is well to retain them. These words are descriptive of *intensity* rather than of *duration*, and therefore the epithet *chronic* is used to imply the length of time that an inflammation has continued, and generally speaking a chronic disease is also subacute, for an acute inflammation, could scarcely exist long enough to be called chronic, for it would either be deprived of its acuteness by active treatment, or it would prove fatal, or assume other characters besides those of simple inflammation. The products and terminations of acute and chronic inflammation differ considerably. We shall now turn our attention to some of the terminations of inflammatory action. The first of these to be noticed, is *resolution*, by which is meant a cessation of the inflammation and its *effects*. This is properly a *termination*, because all is at an end. It is resolved, by a cessation of the increased action of the arteries,—that is to say, it ceases to be true inflammation. This resolution may be effected by blood-letting, which diminishes the force of the circulation, and, by removing the element determination, reduces the inflammation to *congestion*. An example of this is seen after active inflammation in the eye where the vessels remain congested, and only require the application of astringents in order to put an end to the whole process. Sometimes, however, the congestion is removed *with* the determination, the tone of the capillaries being speedily restored. Even slight *inflammations* of mucous membranes may be removed by stimulants and this is effected by the removal of the congestion. The resolution is sometimes accompanied by effusions or hæmorrhages. Slight or subacute inflammation may go on for a considerable time, and yet be afterwards resolved. Sometimes it may be resolved in one part, and then attack an adjoining part, as though there was something moveable in it, and could have its effects transferred from one set of vessels to another, as in erysipelas; this is supposed to arise from continuity of texture: so also in catarrhal inflammations and affections generally of the air passages, there is a great tendency to spreading. The same is the case in the urinary passages; for instance, inflammation commencing in one kidney may proceed down the ureter to the bladder, and thence along the opposite ureter to the other kidney. In inflammation of serous membranes, there is also a proneness to extension. In the mucous membrane of the *intestines* inflammation is generally more circumscribed. Again, we find that inflammation is transferred under other circumstances than can be accounted for on the supposition of *continuity*; thus it may be transferred from the costal to the pulmonary pleura, and the communication is said to arise from *contiguity* of texture. This may have nothing to do with *resolution*, for *both* membranes may remain inflamed together. It is often difficult to say *how* the inflammation is transferred. Again, inflammation sometimes ceases by *metastasis*; this is particularly the case in fibrous membranes. Thus in rheumatism, there may be effusion into a joint which will suddenly disappear and present itself in another joint, and yet no trace whatever remain in the previous seat. This transference must depend upon a *morbific matter*, which is carried about in the circulation, and deposited in various parts. A similar phenomenon is seen in the transference of inflammation from the parotid gland to the testicle. In females, the breasts are affected under similar circumstances. This alternation would seem to arise from analogy in the structure of the different parts. There is a mistake not unfrequently made with regard to the occurrence of Pericarditis as a result of *metastasis* in cases of rheumatism. Now, in the majority of instances, there is no true *metastasis* at all, but simply a *coexistence* of inflammation in the pericardium and other parts. If the inflammation ceased entirely in its first seat, and then attacked the brain or heart alone, it would constitute genuine metastasis, but you will find this rather a rare occurrence.

Resolution, when complete, is marked by the subsidence of all the inflammatory symptoms, viz., heat, redness, swelling, &c.; but there is sometimes, and, indeed not uncommonly a continuation of the irritation of the nerves of the part, especially if the subject be of the nervous temperament—the nerves thus appear to retain the irritation after the vessels have entirely recovered their previous condition. Another point of very considerable importance in connection with the resolution of inflammation, is the constitutional accompaniment that is generally observed to present itself, viz., the occurrence of what is termed a "*critical discharge*." That there commonly is some discharge attending resolution is a fact familiar to every careful clinical observer.—The nature of the discharge may vary—sometimes it consists of perspiration—sometimes it is a diarrhœa, the evacuations containing matters of a greenish or dark brown appearance. Sometimes hæmorrhage is observed to happen at the time of resolution, but the most frequent of any is the deposition in the urine of what is known as lateritious sediment, consisting of the lithate and purpurate of ammonia. The question will here naturally suggest itself to you, whether these discharges, for instance, the deposits found in the urine, are the *cause* of the resolution, or merely the *effects*, and indications that the change has occurred? There is no doubt that during fever the secretions are diminished, the capillaries become constringed, and hence the urine is scanty and high-coloured, and I think it is reasonable to suppose that the discharge just alluded to may simply be the throwing out from the system of the accumulated matters—in fact, a resumption of function. These augmented secretions are, as I told you, called "critical." They indicate the state of the disease, and being satisfactory evidences should always be regarded with attention.

A *second termination* of inflammation generally enumerated, is *effusion*. Now, it will be obvious to you that effusion is, strictly speaking, only a *product* of inflammation, and not necessarily a *termination*; for, although in many cases, the occurrence of effusion *does* relieve the blood-vessels, and the inflammatory action ceases, yet if the determination and congestion *do* continue, the inflammation may, notwithstanding the effusion, still go on. We have an example of inflammation terminating with effusion in the case of *pleurisy*, where lymph being effused, and becoming organized, and forming loose and harmless adhesions, the cure may be perfect. But we shall find that, in most instances, the product itself that is effused gives rise to unquestionable mischief. Suppose, as an illustration of this, that, in a case of pericarditis, a large quantity of lymph is thrown out, which becomes organized, and afterwards contracts, is it not clear that, although no inflammation may continue, the function of the heart is in almost certain danger of being seriously impaired by the shackling of the contracted product? So, again, if the endocardium is the seat of inflammation, the action of the valves of the heart is sure to be more or less impaired. The same principle is equally applicable to the lungs, and also to the intestines; in the case of the latter, the lymph, by the formation of adhesions, impedes the peristaltic action. The injury done is likely, of course, to be yet more serious if, in addition to the effusion of the lymph, the inflammation should continue. Now, there are, as I intimated in a former lecture, several varieties of lymph. If not absorbed, it must either be organized, or remain as a foreign body. In acute inflammations in otherwise healthy subjects, the lymph may be organized so as to differ little from the tissues with which it is in contact, and may be productive of very little inconvenience. When inflammation is less acute, and especially if the patient does not possess a strong constitution, the lymph that is thrown out will be of a *lower* character, and differ materially from the tissue in which it is produced; it [illegible] have a tendency to *contract* and become rigid; [illegible] also less vascular than that before-mentioned, a[illegible] interferes sometimes to a very remarkable degree with the mobility, and consequently with the functions, of the part. The lymph deposited upon serous membranes sometimes becomes exceedingly hard and rigid: it may assume quite a *fibro*-cellular consistence, and, indeed, so great is the induration in some cases, that it appears even fibro-*cartilaginous*. Sometimes the deposition presents a granular form,—this is particularly observed on the peritoneum; such collections may be called tubercular secretions. The lungs exhibit similar products of consolidation, which constitute permanent obstructions. Contractile lymph is found also to occur in the liver, so that, occasionally, the whole organ may become so completely shrunk as to have its functions almost entirely interrupted. Inflammation in fibrous membranes produces *thickening*—this result is seen frequently in the valves of the heart. So, also, on the fibrous tissue investing bones, lymph is first deposited, and afterwards osseous matter; hence arise nodes, &c.

Effusion seems to have a tendency to *lower* the character of inflammation, for it becomes less acute after effusion has taken place; this is shewn by the fact of the matter subsequently thrown out presenting a curdy appearance, proving the lymph to be degenerating in its quality. This degradation is well seen in cases of chronic peritonitis. These lower products, being little capable of organization, are much more mischievous than those of a higher character. We have an instance of a low secretion in empyema, which consists of a mixture of curdy lymph and serum.

On *mucous* surfaces the matter thrown out does not, as I before impressed upon you, cause *adhesions*. The effusion is of a mixed nature, and looks thick and opaque. Besides what is poured *out* upon the surface, some is *retained* within the pores, and occasions thickening and stricture;—thus, in the intestines, bladder, urethra, &c., we find strictures produced by inflammation. This

thickening occurs principally in the *sub*-mucous tissue.

The *symptoms*, or, more correctly, the *signs*, that attend the occurrence of effusion, are *externally*, increased *swelling* and hardness. If the effusion is *internal*, there are also evidences frequently to be obtained: thus, if it happen in a part that can be reached by manipulation, swelling will be discovered, and dulness on percussion will be produced. Signs of displacement of adjoining organs may also be present; as well as obstructions arising from the pressure. The fever may continue nearly as before the effusion occurred, although, *generally*, the strength of the pulse, and the other constitutional symptoms, become somewhat diminished—but the real functional disturbance is often greatly augmented; for example, in the lungs, *after* effusion has taken place, the dyspnœa is almost inevitably aggravated. We may, perhaps, say, that *pain* is usually lessened when effusion occurs, although in some cases it is undoubtedly increased, as where the matter effused is situated under tense membranes.

Effusion of *pus* is much more a termination of inflammation than the effusion of lymph, for pus is developed at the expense of the vessels, and considerably relieves. In abscess, where the inflamed part becomes destroyed, and pus is thrown out, which, by pressure, causes absorption of tissue, we see how the inflammation is resolved—many of the inflamed vessels are removed altogether. The mucous membrane lining the urethra is often greatly relieved by the secretion of pus. When suppuration is established, constitutional weakness is generally substituted for the *excitement* that previously existed. When the pus is collected in an abscess, as in parenchymata, part of the tissue is destroyed, and its place occupied by the purulent secretion. At the commencement of suppuration, there is usually shivering, or, as it is called, a rigor—there are also other symptoms that commonly characterize the formation of pus, with which, I presume, you must be acquainted.

Parts *around* an abscess may still be the seat of inflammatory action, because the collection acts as a foreign body. Most relief is experienced by suppuration when it is circumscribed: the matter, by its pressure, causes absorption in one direction or another; and it generally progresses in the direction in which the tissues are most yielding. In the lungs, and some other parts, there is no circumscription, but the matter is infiltrated throughout the texture. Abscesses occurring internally may produce various accidents on their way to the surface of the body. The protective inflammation that occurs is beautifully adapted to guard it, and prevent its opening into adjoining parts, for lymph is thrown out which forms a boundary to the matter;—this protection is also effected by the formation of adhesion between different membranes. It is also of the greatest importance that the *system*, generally, should be preserved from the influence of the pus, for, when it is diffused, the most baneful consequences are produced.

A New Cranial Saw.—M. Berthérand has invented a saw for cutting the cranium, in examinations after death, and calls it a *cranial cyclotome*. It consists of a saw, concave at one edge and convex at the other, which, by means of a screw, can be turned in its long handle, so as to present either edge at will in the direction for cutting. It is also fitted with a copper conductor, which can be worked in the same way, and fixed at any required distance from the edge, so as to prevent the saw from passing too deeply through the skull.

Remarkable Case of Thoracic Fistula.—A patient labouring under this malady described in a German Journal is a clarionet-player, who notwithstanding this diseased state, can follow his avocation and take long walks. He closes the opening in his side with a cork; and as often as he *uncorks* himself, air mixed with pus passes freely in and out through the aperture.

ART OF COPYING ENGRAVINGS, OR ANY PRINTED CHARACTERS FROM PAPER, ON METAL PLATES, &c.

By Mr. Robert Hunt.*

The Journal of the Academy of Sciences of Paris, for the 18th of July, 1842, contains a communication made by M. Regnault, from M. Moser, of Konigsberg, "Sur la formation des images Daguerriennes;" in which he announces the fact, that, "*when two bodies are sufficiently near, they impress their images upon each other.*" The Journal of the 29th of August contains a second communication from M. Moser, in which the results of his researches are summed up in twenty-six paragraphs. From these I select the following, which alone are to be considered on the present occasion:—"All bodies radiate light even in complete darkness.—This light does not appear to be allied to phosphorescence, for there is no difference perceived whether the bodies have been long in the dark, or whether they have been just exposed to daylight, or even to direct solar light.—Two bodies constantly impress their images on each other, even in complete darkness.—However, for the image to be appreciable, it is necessary, because of the divergence of the rays, that the distance of the bodies should not be very considerable.—To render the image visible, the vapour of water, mercury, iodine, &c., may be used. There exists *latent light*, as well as latent heat."

The announcement at the last meeting of the British Association of these discoveries (*Athen. ante*, p. 687), naturally excited a more than ordinary degree of interest. A discovery of this kind, changing, as it does, the features, not only of the theories of light adopted by philosophers, but also the commonly received opinions of mankind, was more calculated to awaken attention than anything which has been brought before the public since the publication of Daguerre's beautiful Photographic process. Having instituted a series of experiments, the results of which appear to prove that these phenomena are not produced by *latent heat*, I am desirous of recording them.

I would not be understood as denying the absorption of light by bodies; of this I think we have abundant proof, and it is a matter well deserving attention. If we pluck a Nasturtium when the sun is shining brightly on the flower, and carry it into a dark room, we shall still be enabled to see it by the light which it emits. The human hand will sometimes exhibit the same phenomenon, and many other instances might be adduced in proof of the absorption of light, and I believe, indeed, of the principle that light is latent in bodies. I have only to show that the conclusions of M. Moser have been formed somewhat hastily, being led, no doubt, by the striking similarity which exists between the effects produced on the Daguerreotype plates under the influence of light, and by the juxta-position of bodies in the dark, to consider them as the work of the same element.

1. Dr. Draper, in the Philosophical Magazine for September, 1840, mentions a fact which has been long known, that "if a piece of very *cold* clear glass, or what is better, a *cold* polished metallic reflector, has a little object, such as a piece of metal, laid on it, and the surface be breathed over once, the object being then carefully removed, as often as you breathe again on the surface, a spectral figure of it may be seen, and this singular phenomenon may be exhibited for many days after the first trial is made." Several other similar experiments are mentioned, all of them going to show that some mysterious molecular change has taken place on the metallic surface, which occasions it to condense vapours unequally.—2. On repeating this simple experiment, I find that it is necessary for the production of a good effect, to use dissimilar metals; for instance, a piece of gold or platina on a plate of copper or of silver, will make a very decided image, whereas, copper or silver on their respective plates give but a very faint one, and bodies, which are bad conductors of heat, placed on good conductors, make decidedly the strongest impressions when thus treated.—3. I placed upon a well polished copper plate, a sovereign, a shilling, a large silver medal, and a penny. The plate was gently warmed by passing a spirit lamp along its under surface; when cold, the plate was exposed to the vapour of mercury; each piece had made its impression, but those made by the gold and the large medal were most distinct; not only was the disc marked, but the lettering on each was copied.—4. A bronze medal was supported upon slips of wood, placed on the copper, one-eighth of an inch above the plate. After mercurialization, the space the medal covered was well marked, and for a considerable distance around the mercury was unequally deposited, giving a shaded border to the image.—5. The above coins and medals were all placed on the plate, and it was made too hot to be handled, and allowed to cool without their being removed; impressions were made on the plate in the following order of intensity—gold, silver, bronze, copper. The mass of the metal was found to influence materially the result; a large piece of copper making a better image than a small piece of silver. When this plate was exposed to vapour, the results were as before (3, 4). On rubbing off the vapour, it was found that the gold and silver had made permanent impressions on the copper.—6. The above being repeated with a still greater heat, the image of the copper coin was, as well as the others, most faithfully given, but the gold and silver only made permanent impressions.—7. A *silvered* copper plate was now tried with a moderate warmth (3). Mercurial vapour brought out good images of the gold and copper; the silver marked, but not well defined.—8. Having repeated the above experiments many times with the same results, I was desirous of ascertaining if electricity had any similar effect; powerful discharges were passed through and over the plate and discs, and it was subjected to a long-continued current without any effect. The silver had been cleaned off from the plate (7); it was now warmed with the coins and medals upon it, and submitted to discharges from a very large Leyden jar; on exposing it to mercurial vapour, the impressions were very prettily brought out, and, strange to say, spectral images of those which had been received on the plate when it was silvered (7). Thus proving that the influence, whatever it may be, was exerted to some depth in the metal.—9. I placed upon a plate of copper, blue, red, and orange coloured glasses, pieces of crown and flint glass, mica, and a square of tracing paper. These were allowed to remain in contact half-an-hour. The space occupied by the red glass was well marked, that covered by the orange was less distinct, but the blue glass left no impression; the shapes of the flint and crown glass were well made out, and a remarkably strong impression where the crown glass rested on the tracing paper, but the mica had not made any impression.—10. The last experiment repeated; after the exposure to mercurial vapour, heat was again applied to dissipate it, the impression still remained.—11. The experiment repeated, but the vapour of iodine used instead of that of mercury. The impressions of the glasses appeared in the same order as before, but also a very beautiful image of the mica was developed, and the paper well marked out, showing some relation to exist between the substances used and the vapours applied.—12. Placed the glasses used above (9, &c.), with a piece of well smoked glass, for half-an-hour, one-twelfth of an inch below a polished plate of copper. The vapour of mercury brought out the image of the smoked glass only. 13. All these glasses were placed on the copper and slightly warmed: red and smoked glasses gave, after vaporization, equally distinct images, the orange the next, the others left but faint marks of their forms; polishing with Tripoli and putty powder would not remove the images of the smoked and red glasses.—14. An etching, made upon a smoked etching ground on glass, the copper and glass being placed in contact. The image of the glass only could be brought out.—15. A design cut out in paper was pressed close to a copper plate by a piece of glass, and then exposed to a gentle heat; the impression was brought out by the vapour of mercury in beautiful distinctness. On endeavouring to rub off the vapour it was found that all those parts which the paper covered

* For this interesting paper we are indebted to our able contemporary, the *Athenæum*.

amalgamated with mercury, which was removed from the rest of the plates; hence there resulted a perfectly permanent white picture on a polished copper plate.—16. The coloured glasses before named (9, 12), were placed on a plate of copper, with a thick piece of charcoal, a copper coin, the mica, and the paper, and exposed to fervent sunshine. Mercurial vapour brought up the images in the following order—smoked glass, crown glass, red glass, mica beautifully delineated, orange glass, paper, charcoal, the coin, blue glass; thus distinctly proving, that the only rays which had any influence on the metal, were the calorific rays. This experiment was repeated on different metals, and with various materials, the plate being exposed to steam, mercury and iodine; I invariably found, that those bodies which absorbed or permitted the permeation of the most heat, gave the best images. The blue and violet rays could not be detected to leave any evidence of action, and as spectra imprinted on photographic papers by light which had permeated these glasses, gave evidence of the large quantity of the invisible rays which passed them freely, we may also consider those entirely without the power of effecting any change on compact simple bodies.—17. In a paper which I published in the Philosophical Magazine, for October 1840, I mentioned some instances in which I had copied printed pages and engravings on iodized paper, by mere contact and exposure to the influence of the calorific rays, or to artificial heat. I then, speculating on the probability of our being enabled by some such process as the one I then named to copy pictures and the like, proposed the name of THERMOGRAPHY, to distinguish it from Photography.—18. I now tried the effects of a print in close contact with a well-polished copper-plate. When exposed to mercury, I found that the outline was very faithfully copied on the metal.—19. A paper ornament was pressed between two plates of glass, and warmed, the impression was brought out with tolerable distinctness on the under and warmest glass, but scarcely traceable on the other.—20. Rose leaves were faithfully copied on a piece of tin plate, exposed to the full influence of sunshine, but a much better impression was obtained by a prolonged exposure in the dark.—21 With a view of ascertaining the distance at which bodies might be copied, I placed upon a plate of polished copper, a thick piece of plate glass, over this a square of metal, and several other things, each being larger than the body beneath. These were all covered by a deal box, which was more than half an inch distant from the plate. Things were left in this position for a night. On exposing to the vapour of mercury, it was found that each article was copied, the bottom of the deal box more faithfully than any of the others, the grain of the wood being imaged on the plate.—22. Having found, by a series of experiments, that a blackened paper made a stronger image than a white one, I very anxiously tried to effect the copying of a printed page or a print. I was partially successful on several metals, but it was not until I used copper-plates amalgamated on one surface, and the mercury brought to a very high polish, that I produced anything of good promise. By carefully preparing the amalgamated surface of the copper, I was at length enabled to copy from paper line-engravings, wood-cuts, and lithographs, with surprising accuracy. The first specimens produced (which were submitted to inspection), exhibit a minuteness of detail and sharpness of outline quite equal to the early daguerrotypes and the Photographic copies, prepared with chloride of silver.*

The following is the process at present adopted by me, which I consider far from perfect, but which affords us very delicate images. A well-polished plate of copper is rubbed over with the nitrate of mercury, and then well washed to remove any nitrate of copper which may be formed; when quite dry, a little mercury taken up on soft leather or linen, is well rubbed over it, and the surface worked to a perfect mirror. The sheet to be copied is placed smoothly over the mercurial surface, and a sheet or two of soft, clean paper being placed upon it, is pressed into equal contact with the metal by a piece of glass, or flat board; in this state it is allowed to remain for an hour or two. The time may be considerably shortened by applying a very gentle heat for a few minutes to the under surface of the plate. The heat must on no account be so great as to volatilize the mercury. The next process is to place the plate of metal in a closed box, prepared for generating the vapour of mercury. The vapour is to be slowly evolved, and in a few seconds the picture will begin to appear; the vapour of mercury attacks those parts which correspond to the white parts of the printed page or engraving, and gives a very faithful but somewhat indistinct image. The plate is now removed from the mercurial box, and placed in one containing iodine, to the vapour of which it is exposed for a short time; it will soon be very evident that the iodine vapour attacks those parts which are free from mercurial vapour, blackening them. Hence there results a perfectly black picture, contrasted with the grey ground formed by the mercurial vapour. The picture being formed by the vapours of mercury and iodine, is of course in the same state as a Daguerrotype picture, and is readily destroyed by rubbing. From the depth to which I find the impression made into the metal, I confidently hope to be enabled to give to these singular and beautiful productions a considerable degree of permanence, so that they may be used by engravers for working on. It is a curious fact, that the vapours of mercury and of iodine attack the plate differently, and I believe it will be found that vapours have some distinct relation to the chemical or thermo-electrical state of the bodies upon which they are received. Moser has observed this, and attributes the phenomena to the colours of the rays, which he supposes to become latent in the vapour on its passing from the solid into the more subtle form. I do not, however, think this explanation will agree with the results of the experiments. I feel convinced that we have to deal with some thermic influence, and that it will eventually be found that some purely calorific excitement produces a molecular change, or that a thermo-electrical action is induced, which effects some change in the polarities of the ultimate atoms of the solid.

These are matters which can only be decided by a series of well-conducted experiments. Although attention was called to the singular manner in which vapours disposed themselves on plates of glass and copper, two years since by Dr. Draper, Prof. of Chemistry at New York, and about the same time to the calorific powers of the solar spectrum, by Sir John Herschel, and to the influence of heat artificially applied, by myself (17), yet it is certainly due to M. Moser of Konisberg, to acknowledge him to be the first who has forcibly called the attention of the scientific world to an inquiry which promises to be as important in its results as the discovery of the electric pile, by Volta.

* The first faithful copy of the lines of a copper-plate engraving was obtained by Mr. Cantabrana, who has since succeeded in procuring some tolerable specimens on amalgamated copper, which cannot be rubbed off.

CALOMEL IN OPHTHALMIA NEONATORUM.—Calomel in this case is spoken of by German writers as very successful. The manner of introducing the calomel into the eye is by means of a camel's hair pencil loaded with the powder, which is shaken from it into the eye, while an assistant separates the lids. In the treatment of the ophthalmia neonatorum this remedy may be had recourse to as soon as the first traces of the disease appear, and its employment once daily is then in general sufficient. After the lapse of from half an hour to two hours, according to the quantity of the secretion, the eye may be washed from the powder, and the ordinary rules as to cleanliness be attended to. In severe cases the application may be repeated twice every day; but when the disease is mild a single application daily suffices to effect a cure in from four to ten days, if the remedy had been had recourse to from the outset. The more severe and infractable forms of the disease do not appear to have been benefitted by the local employment of calomel.

LECTURES ON CHEMISTRY.

By JOHN SCOFFERN, M.B., Lecturer on Chemistry, at the Aldersgate School of Medicine.

I purpose in this lecture continuing our examination of the chemical agencies of voltaic electricity and, as a necessary prelude to this subject, I will remind you, that when speaking of chemical attraction or affinity, I stated we had no means whatever of estimating its real amount; but it was most rational to assume, that when many compounds were formed by the union of two bodies in several proportions, the most permanent body, the one in which the form of affinity was strongest, would be constituted of single atoms. Hence it would follow, according to the electro-chemical theory of Davy, that bodies of this class, and which are known to chemists under the name of *proto*-compounds, as *protoxides*, *protochlorides*, and the like, should, amongst others, require the greatest amount of voltaic energy for their decomposition. Almost every experiment that we can devise appears to demonstrate that the elements of proto-compounds are held together with greater force than their corresponding associates. I take (as an example almost at random), the two principal compounds of lead and oxygen—the protoxide and the peroxide. I heat the former, without producing any change in its constitution, but by heating the latter, I drive off oxygen, and it is reduced to the condition of protoxide. This experiment shows that one is more stable than the other, the protoxide being most so.

Entering, then, upon the study of voltaic decomposition, with such ideas as this experiment naturally gives rise to, we should not expect that proto-compounds would be very easily decomposed; certainly not with greater ease than their associates: yet Faraday has demonstrated that the former *alone* are capable of decomposition by the *direct* or *primary* agency of voltaic electricity. Other secondary agencies frequently modify the result a good deal, and they misled former experimenters, but we shall do well to disregard them altogether. Remember, then, that only proto-compounds, so far as we know, are capable of direct voltaic decomposition; although we have every reason to believe that in the constitution of such, there is lavished the very maximum of affinity. So universal is this result on known proto-compounds, that we sometimes appeal to it for determining a doubtful case. Thus, it was doubted, and is now by some, whether the liquid *water* be actually a proto-compound or otherwise; but it is easily decomposed by voltaic electricity, and therefore to be in accordance with the best analogies, we must pronounce it a proto-compound.

I need scarcely indicate how diametrically opposed these results are to the deductions of Sir H. Davy's theory; which assumes that every compound should be decomposable by a sufficient amount of voltaic force, and first of all, those compounds which have the weakest affinities. This discovery was made by Faraday, who also proved that the same amount of electricity always decomposed equal equivalent or *atomic* quantities of different decomposable substances, and that hence there might be indicated electrical as well as chemical equivalents. The remark will be more evident after an examination of the accompanying illustration:

9 grs. of water are composed of	8 grs. oxygen + 1 gr. hydrogen
37 grs. of hydrochloric acid, of	36 „ chlor. + 1 „ ditto
15 grs. chloride of silver, of	36 „ ditto + 103 „ silver
230 grs. of iodide of lead, of	103 „ iodine + 101 „ lead

Now any electrical force which is capable of decomposing 9 grains of water into its elements, will also decompose 37 grains of hydrochloric acid, 115 grains of chloride of silver, and 230 grains of iodide of lead. If we insist upon the absolute identity of chemical and electrical agencies, we are led to a very curious deduction—namely, that

the elements of all compounds decomposable by voltaic electricity are united with equal force; in other words, that there exist no differences between the amount of their chemical affinities, because we have seen that the same amount of electrical force will separate into their respective elements 9 grains of water, 37 of hydrochloric acid, &c. Thus, so far as relates to proto-combinations, we should accept the philosophy of Berthollet, who believed that the attractions existing between the elements of compounds were all equal; or, more properly speaking, that there was no such force as *chemical attraction* in existence.

Besides demonstrating the fact, that there might be instituted electro-chemical equivalents, and that none but proto-combinations were susceptible of voltaic decomposition, Faraday proved by a series of well-concerted experiments, that the poles or ends of a battery had (in the correct acceptation of the term) no attractive force; that elements proceeded thither not on account of an attractive influence *merely* soliciting them, but on account of a force generated within themselves impelling or determining them: that in point of fact, such bodies, during decomposition, were not to be regarded as extraneous to the battery, and merely acted upon by it, but that they actually formed part of the battery, and necessarily reciprocated any force recognisable in any other part of that battery.

Finding the theory of Davy imperfect, and being solicitous lest these imperfections should be perpetuated by terms in use, Dr. Faraday has introduced certain others into philosophical language, which I will now describe. In the first place then, since all compounds are not decomposable by direct voltaic influence, it would be well to coin a term, indicative of those which are: the term electrolyte is concise and expressive, and indeed answers every purpose. It originates in two Greek words, signifying *amber*, and *to loosen, or separate*; and its indication are sufficiently plain without any comment. The term electrolize, expresses the act of volta-electrical decomposition. Unfortunately associated as is the term of *pole* with an attractive influence, Faraday very properly objects to it. He maintains that the ends, or so-called poles of a voltaic arrangement are merely the doors, or ways through which the electricity moves, and that if certain bodies are found near either one or the other, it is not because they are attracted there; but they are determined in *that direction*, and can get no farther on account of the solid and unyielding nature of the ends or poles. This, Faraday verified by making the so called poles of liquid or yielding materials, in which case the elements of a decomposed compound proceeded on till they met with some opposing solid. For these reasons the term *electrode* was invented from a Greek word signifying *away*. Furthermore, the one fluid theory of Franklin was adopted as convenient in these cases, and it was assumed that electricity entered upon its course at the positive end, and terminated it at the negative: the rising and setting sun were the ideas which suggested themselves to Faraday as analogous to this case, therefore, he called the positive or emitting end, the anode, and the negative, or receiving end, cat-ode, or cathode, downwards. Again, the propriety of the terms electro-positive and electro-negative was disputed, inasmuch as bodies could not be proved to possess naturally either kind of electricity. Elements which were capable of being determined to either end of a voltaic arrangement, he called ions, from the Greek to go; Thus we have anions, or bodies which go to the positive pole (electro negatives), and cathions or electro positives. I call your attention to a table of simple and compound ions, that is, bodies which have been proved capable of being separated from their compounds by voltaic agency.

ANIONS.

Oxygen	Selenic acid	Tartaric acid
Chlorine	Nitric acid	Citric acid
Iodine	Chloric acid	Oxalic acid
Bromine	Phosphoric acid	Sulphur
Fluorine	Carbonic acid	Selenium
Cyanogen	Boracic acid	Sulphocyanogen
Sulphuric acid	Acetic acid	

CATIONS, OR CATHIONS.

Hydrogen	Cadmium	Lithia
Potassium	Cerium	Baryta
Sodium	Cobalt	Strontia
Lithium	Nickel	Lime
Barium	Antimony	Magnesia
Strontium	Bismuth	Alumina
Calcium	Mercury	Protoxides—generally
Magnesium	Silver	Quinia
Manganese	Platinum	Cinchonia
Zinc	Gold	Morphia
Tin	——	Vegeto alkalis—generally
Lead	Ammonia	
Iron	Potassa	
Copper	Soda	

Carbon, phosphorus, nitrogen, silicon, boron, and aluminium, have not yet been experimentally proved to be ions, although analogy leads us to suppose they are. Amongst compound bodies, the same uncertainty exists in regard to the compounds silica and alumina. On account of these doubtful cases it will be seen that, although the terms, anion and cathion, are more correct than those of electro-positive and electro-negative, yet for the purposes of chemical classification, the latter are, perhaps, more generally useful, inasmuch as no substance can be called an anion except it has been proved capable of going to the anode, and *vice versa*, whereas strong analogies have been thought sufficient to entitle it to the name of *electro-negative*. In all cases of voltaic decomposition two elements are determined in certain directions, one to either end of the battery. Supposing water to be the example, we find hydrogen to be liberated at the negative or cathode, and oxygen at the other. Now, no particle of hydrogen can be liberated, without setting free a particle of oxygen, and no particle of oxygen without eliminating one of hydrogen; an interesting question arises, then, in connection with this phenomenon: what becomes of the particles thus set free? It would seem, judging from the ultimate effects of the battery, that the bulk of a decomposing fluid must be traversed continually by these two kinds of particles, each going in an opposite direction, but invisibly. I believe Grotthus was the first who explained this, by assuming that each simple particle of a compound substance between the two poles or electrodes, combined with its opposite, so as continually to regenerate the compound,—a state of things which may be roughly assimilated to a continual change of partners in walking down a country dance; or, if you do not consider my illustration particularly happy, perhaps the accompanying literal one will be more fortunate. Water is composed of oxygen and hydrogen, as you are aware; therefore, it may be indicated thus **OH** Suppose a portion of water, about to have voltaic electricity passed through it in the direction of the arrow to be indicated thus

+ OH OH OH −

The signs + and −, representing the anode and cathode respectively. Then it is presumed that the particles, in order to bring themselves into proper position, revolve over each other in a cycle, either right or left handed, according as the electric current might vary in direction. In this instance the cycle would be right handed, and the particles in their intermediate condition would stand thus

+ H O O O −
H H

preparatory to their being brought thus

+ OH OH −

as originally; when, of course, the remaining oxygen and hydrogen would have to change partners again, and leave them as before, until all became decomposed. In Faraday's words, "The current is an axis of power, equal, and exerted in opposite directions, by which, in every case of a true binary compound, the molecules of one element are carried in one direction, while those of the other constituent move in the reverse course." It will have been gathered from this lecture, that Faraday agrees with Wollaston in attributing the whole of voltaic electricity to chemical action; indeed, he goes farther, and believes that every case of chemical action must give rise to electricity. If this theory be correct, we ought not to be under the *necessity* of referring to particular forms of apparatus for the sake of witnessing the effects of voltaic electricity, although such particular forms might be most convenient. We ought to be able to take any case of chemical action at random for this purpose, or, at all events, the supposition of our taking it ought not to seem an absurdity.

We have seen that the most powerful voltaic arrangements are those in which there are two metals and a fluid; the latter being only capable of acting upon one metal. If we dispense with the second metal we may generally have chemical action, but we destroy our voltaic arrangement. This is satisfactory, for it proves that the addition of a second metal increases chemical action on the first, and we may easily imagine the forces determining combination to be so nicely balanced, that without this second metal no combination would result at all. The use of this second piece of metal in a voltaic arrangement appears to be that of restoring by its conducting power the electrical equilibrium of the other two, an equilibrium which their chemical union as immediately disturbs. Hence the more readily this equilibrium is restored, the more rapid may we suppose the chemical union to be. Although the perfection of a voltaic current is insured by the presence of a second metal, yet when bodies have a tendency to unite, it would be difficult, if not impossible, to prevent those currents altogether; hence we may easily suppose chemical and voltaic actions to be always simultaneous, although we cannot trace, in the majority of instances, the most perfect conditions, indicated by a knowledge of voltaic electricity. By availing ourselves of those conditions, however, we can generally exalt the chemical energies, although by doing the contrary to the utmost of our power, we cannot always abolish them altogether. Our time does not admit of my treating voltaic electricity more in detail. I regret my inability from this cause, to mention the numerous applications which have been made of this most wonderful agent. I cannot, however, conclude without drawing your attention to the beautiful arts of electrotype, and electro-gilding. To practice these arts with success much experience is requisite; but their theory is very easy, and may be explained in a few words: indeed, you are already aware, perhaps unconsciously, of the process to be followed. You remember the principle of action of the constant battery—how a layer of copper was caused to be deposited on the original copper!—Well, if this original copper had been engraved, of course the deposited metal would have assumed the same pattern,—thus I very briefly explain to you the nature of electrotype. By acting on solutions of gold and silver we can deposit these metals; these are the processes, called respectively electro-gilding and silvering.

GUNSHOT WOUND.

SECONDARY HÆMORRHAGE AND LIGATURE OF THE COMMON CAROTID ARTERY.

By William Smith, Esq., Surgeon.

(For the "Medical Times.")

PRIVATE NEWELL, of the 1st Regiment of the British Auxiliary Legion, during an attack upon the enemy's lines in front of St. Sebastian on the 5th of May, 1837, was hit by a musket ball, which pierced the superciliary ridge of the frontal bone towards its external angle, on the left side of the head; from thence it entered the back part of the orbit, and made its exit on the superior and posterior aspect of the pharynx of the same side. It now proceeded across the cavity of the mouth, and entered the lower portion of the pharynx on the opposite side and proceeding downwards and forwards, it lodged under the lower third of the sterno cleido-mastoideus muscle of the

right side of the neck. The site of the ball was not discovered immediately after the receipt of the injury, nor until after death.

The case was conveyed to the General Military Hospital of St. Zelmo, in St. Sebastian, the same evening on which the wound was received; and the patient seemed to go on favourably until the afternoon of the 11th., or the 8th. day after the accident. On that day I was doing the duty of orderly medical officer at the hospital, and about five in the afternoon I was called to see Newell, who, I was told, was bleeding at the mouth. On arriving at his bed, I found a small quantity of arterial blood flowing; and directed him to gargle his mouth with cold water, and which being done, the hæmorrhage stopped. On examining the cavity of the mouth, which I did previously to ordering the gargle, I discovered the wounds on the right and left side of the pharynx, and I at the same time saw the blood issuing in a small quantity from that on the left. The case not being under my charge, excepting in so far as my routine of orderly duty was concerned, this was the first time I had examined it particularly. In addition to gargling the mouth I ordered cold water to be constantly applied to the external wound and forehead, hoping by these means, to put a stop to the hæmorrhage if the vessel should be small. From the apparent direction of the wound, I had little doubt but that some of the branches of the internal carotid were injured and most probably the internal maxillary.

Having given these directions, with orders that he should be punctually watched, I left him for that time. About midnight I was again called to him, and informed by the orderly, that he was now bleeding profusely by the mouth. I saw him immediately, and found the bed as well as the floor on one side, covered with blood to the extent perhaps of about lbii.s. I now immediately propo.ed taking up, and securing the external carotid artery, in order to save him, to which proceeding he immediately and gladly consented. There was at this period great pain on the right side of the neck, where the ball was located, and on this account I felt some difficulty in making him bend his neck laterally, so as to expose the left side, on which I intended to operate. By this time I had procured the assistance of the hospital dispensor Mr. Cupples, with two or three of the ward orderlies to stand by in readiness. I commenced the operation by the light of a couple of small candles.

With a couple of pillows under his neck, and lying on his right side, I made a longitudinal incision through the skin and a portion of the integuments, about three inches long, from the lobe of the ear to the middle of the neck, in direction of the sheath of the common carotid and its bifurcation. I very soon got into the sheath, a little under the bifurcation of the vsssel, but my light being very insufficient, I thought I should cut more safely by cautiously pushing in a small grooved director between the anterior part of the vessel and its sheath, as far as the bifurcation. I did so, and ran the bistoury along it, but lo, and behold! the blood issued from my incision in a full arterial stream; so that I thought at the moment that I had cut either the external or the internal carotid right across. By pressing my finger, however, firmly upon the common carotid, which I had now full power of, I cleaned and examined my incision, and found that matters were not so bad as I had apprehended; I had only cut across the superior thyroid artery, which in this case had taken its origin from the trunk of the common carotid. I placed a ligature upon it without delay, and now judged it my best plan to tie the common carotid at the point where I first exposed it. This was completed in a few minutes, and the wound of the integuments was clo.ed with three interrupted sutures and adhesive plaister. The hæmorrhage was completely arrested; but his pulse was weak and compressible. At 5 in the morning he became unable to articulate; and at 7 he was comatose. He died at half-past 8 A.M., eight hours after the operation.

Sectio cadaveris, at 3 P.M. The ball had struck the outer angle of the left orbital or superciliary ridge of the frontal bone, fracturing a portion and descending through the floor of the orbit at its posterior part. It had passed close to the optic nerve, but without injuring it, or fracturing the orbital plate of the frontal bone. From thence it had passed in a direc line to the posterior part of the pharynx, and made its exit on a line parallel to the last molar tooth of the upper jaw, to the left of the mesial line. It had again entered on the lower and opposite side of the pharynx, fracturing the internal and external pterygoid processes of the sphenoid bone of the right side, brushed through between the external and internal carotid arteries, without injuring either of them or their accompanying veins, and lodged under the belly of the sterno-cleido-mastoideus muscle, in the lower third of its extent. There it was found surrounded by a large quantity of coagulated blood. The coats of the eye were uninjured to appearance, but the aqueous and vitreous humours were similar to coagulated blood. The crystalline lens was soft, and almost approaching to fluidity. On opening the tumour on the right side of the neck, the whole space from the clavicle to the mastoid process of the temporal bone was in a complete mass of disorganisation; and it was only with the greatest difficulty that the great blood-vessels could be discovered. On laying open the abdomen, the stomach was found filled with coagulated blood; and from the pylorus to the rectum, the intestines were filled with the same. From the circumstance of the stomach and intestines being thus filled with blood, it would appear that the hæmorrhage had commenced at a considerable time previous to the operation, undiscovered—or before it had issued from the mouth. Perhaps during the sleep in which the patient had fallen between my first and second visits to him on the night of the operation, the vessel or vessels had poured out blood in such quantity as was found in the stomach and intestines; and which had prevented the success of the operation, by the loss of such a large quantity of the vital fluid which the operation was now performed too late to preserve.

EXTRACTS FROM FOREIGN JOURNALS.

(Translated from the Berlin Medical Gazette for the "Medical Times.")

GERMAN.—*Account of the relative number of Births and Deaths in the Prussian States in* 1841, *compared with those of* 1840. By DR. HOFFMAN, Director of the Bureau of Statistics.—This is an interesting paper, especially to those who are engaged in the study of statistics; the following are the principal facts.

In 1841, in the eight provinces of Prussia, except the Principality of Neufchatel, but including the whole military, the population is now, 1842, males, 7,448,582; females, 7,479.919; total, 14,928,501. In 1841, were born 591,505; died 415,256; increase 176,249. The difference of the sexes born, as follows:—

Born in wedlock, males	283,027
—— Females	266,349
Out of wedlock, males	21,419
—— Females	20,710
Legitimate total	549,376
Illegitimate total	42,129
	591,505
Among the births, cases of twins .	6,277
Triple births	67
Quadruple births	3
The number of still-born were .	22,754

Number of deaths at different periods of the year.

Jan. Feb. Mar.	124,416
April, May, June, ...	96,405
July, Aug. Sept.	91,503
Oct. Nov. Dec..	102,932
Total	415,256

The deaths are divided into periods, which are, still-born, the 1st. year after birth, from thence to the end of the 3rd. year, then to the 7th. 14th. 20th; after, in periods of five years, to above eighty. Among the different causes of death given in the paper, are the suicides; the number, of which are, males 1,305; females, 325: total, 1,630; giving the proportion to the whole population, males is 1 to 5.708—females, 1 to 23.015.

Strangulation of the Os Uteri, caused by a ring-Pessary.—The patient, the wife of a farmer, had some years before suffered from prolapsus uteri, for which she had pushed up the vagina a wooden ring; it had the effect of keeping up the uterus, but soon produced painful effects. She was at length obliged to keep her bed. Upon examination, the os uteri was found projecting through the eye of the pessary, forming an elastic fleshy cylinder $2\frac{1}{2}$ inches long, $1\frac{1}{2}$ inch in diameter, which the writer compares to a paraphymosis; above this was found the wooden ring full $2\frac{1}{2}$ inches in diameter—its eye might be an inch in diameter, through which had passed the neck of the uterus, which was so pressed, as to form the cylinder above-mentioned; yet not so much strangulated as to prevent the outflow of the menstrual secretion. The vagina was much excoriated and painful; the treatment was antiphlogistic; the os uteri well scarified and rubbed every two hours with iodine ointment and opium, solution of lead applied freely to the vagina, and its walls smeared with ung. saturn; the ring after the reduction of the swollen os uteri, was at length extracted piece-meal by strong nippers.

Malformation of the Parts of Generation.—In a child eighteen days old, which died from bronchitis. Close under the navel the bladder projected, forming a roundish, spongy feeling, dark red tumour, about the size of a walnut. The mons veneris was consequently wanting, and the regio hypogastrica appeared remarkably shortened. The openings of the ureters lay at the under part of the tumour, hidden in a furrow, and observable only in the dead subject, from which the urine was continually oozing out, keeping the child constantly wet. The Penis was about half an inch in length, flattened, without any urethral passage, instead of the prepuce it was surrounded by two strong, lip-like, dark red folds of skin, which commenced in the furrow beneath the bladder, continuing below into the well-formed scrotum. On the back of the penis ran a shallow channel from before to behind, as it

were the rudiment of the absent urethra. In the scrotum, which was not so large as is usual with new-born boys, yet otherwise well formed, the testes and epididymes lay on each side of the raphe. On the section, the internal urinary and sexual organs showed nothing abnormal except the more spongy than membranous appearance of the urinary bladder. The vasa deferentia were continued as far as the furrow between the bladder and penis; no trace of ossification was found in the pubis; the cartilaginous rudiments of these bones stood quite an inch apart from each other. The abdominal muscles were generally little developed; the pyramidales entirely absent.

Hereditary Phymosis.—Five brothers are mentioned, who, as well as their father, had congenital phymosis. They were cured by circumcision, by Dr. Rupprecht.

Sudden Dumbness.—In consequence of a fright and quarrel with her husband, a very choleric woman suddenly and completely lost the use of her speech, and remained so three weeks; the curative means were first an emetic, then decoct. sinap. internally and washing the mouth with the same; chewing pepper, horse radish, &c., and applying blisters to the back of the neck—speech returned by degrees—she was quite well in six months.

Exit of a Stone from the Bladder through an Abscess in the Rectum.—Nature in this case ejected a stone from the bladder of the size of a walnut, by the same way in which art by the sectio lateralis would have extracted it, and with greater danger to life.

FRENCH.—*On the Origin of Organic Forms.* By M. VIREY.—The subject of the *origin of organic forms* has not hitherto received its due consideration. According to the system of pantheism, we are compelled to admit the *spontaneous formation* even of man and the larger animals, from all eternity, and by a species of fatalism, without the intervention of any distinct or superior intelligence, or by the activity of matter alone. But, if there are evident proofs in natural history: 1st. That organized beings are connected one with another by harmonious relations, according to a regular system; 2nd. That races are not arbitrarily developed, that they establish even insurmountable limits between species, however near allied, and are opposed to the creation of intermediate or permanent hybrid races; 3rd. Lastly, that obstacles are found to exist to the pretended spontaneous, free or physico-chemical generations; we must admit that the production of organic forms does not result from chance or from material circumstances only; a fact of the highest importance; for it would lead us to acknowledge a distinct, and infinitely fore-seeing cause in the generation of *vegetable* and *animal* beings; a cause producing such a chain of relations, and so regular a system of organization. This concatenation of the natural families of organised beings, both vegetable and animal, has long been acknowledged. The ancient philosophers, while admitting spontaneous and irregular generations, had no distinct idea as to the chain of beings and their connections. Aristotle however, in his grand classifications still acknowledged as the bases of zoology, paid great attention to their principal relations of structure. Hence arose his discovery of the symmetrical system pervading nature, which could not possibly result from a fortuitous concourse of inorganic elements or atoms. In fact, the various *species* or *types* presented on our globe are not isolated and unconnected, they belong to an harmonious whole: attesting their common parentage or origin by their intimate *alliances* and *affinities*. Some have asserted that by an original union between distant branches of the creation, repeated at various periods during the long course of ages, has arisen that infinite multitude of races more or less allied, which, successively mingling one with another, have generated that vast hierarchy of species linked together by similar genera and families. Hence, it is said, the unity, the harmony, which appears to pervade the numerous classes of beings, binding together their various elements. Hence, our inability to fix *assignable limits to species and their varieties*, by reason of their various causes of modification from climate, temperature, food, &c. We cannot therefore—it is asserted—wonder at those innumerable races of insects, and plants, in various regions, at their mutual relations and anastomoses. But this theory supposes the possibility of free unions, of a promiscuous intercourse, as it were, between all animal or vegetable species; producing an universal and unrestrained degeneracy throughout the whole globe; leaving no fixed or determined type, but resulting in forms incessantly changing.

We have examined, in the various classes of animals and vegetables, the obstacles opposed to this promiscuous connection of species and confusion of organised nature. There is not only a *law of variety* in the organic productions of our globe, but also an *order of fixity* in the constancy and separation of the types, or the preservation of their original purity, since the *varieties* return spontaneously to their *native standard*, by a succession of oscillations, resembling as it were the pendulum of a clock. Among the conditions of the existence of beings, one of the least remarkable but most essential, is that which *limits the crossing* of species, or which maintains the *prototype* forms. This fact is in itself an evidence against the spontaneousness of organic formations, or their production at *hazard*. In the case of hybrids or mules, we see an alliance between proximate *species*, but not between different *genera*. Thus the carnivora do not mingle themselves with the herbivora; there are assigned limits beyond which the mingling of distinct organisations cannot take place. This law is of equal application in the vegetable kindom, where nature distinguishes the specific types by ingenious constructions. Thus the fecundating pollen, from its form, its size, or the circumstances of flowering time, is unable to fertilize the ovary of every flower or penetrate within the style; it requires certain intimate connexions and fitting periods for fecundation to take place. This isolation of species becomes essentially necessary among aquatic animals, the fish, the inferior races of so many myriads of mollusca, and zoophytes, scattering their spawn upon the waters. Thus each species of ovum undoubtedly accepts and can absorb only the liquid emanating from its normal type, which alone is capable of vivifying it. Hybrids are rare among them. This law of isolation is in like manner fully borne out among insects, some races of which, as the *hymenopteri*, carry a scaly apparatus around the valva, which effectually prevents sexual union with the males of other species.

The ancient notions admitted with regard to the formation of centaurs or satyrs, are disproved, says M. Virey, by the differences in the periods of fecundity, in the duration of gestation, and the mode of nutrition of the various embryos and of the fœtus in the maternal womb. Each species is borne by an irresistible instinct to its *type of normal unity*, of *beauty* or *perfection* in the important act of reproduction; and the blood revolting at all impure and monstrous connections, assists in accomplishing an eternal separation between the different species.

The objection of *spontaneous generations* might be formidable, inasmuch as it gives to nature the power of producing not only all sorts of irregular and unnatural forms, but would even make her an accomplice of each monstrosity, and governed by no defined limits or laws. In this system of pantheism we have no term to the multiplicity of contingent combinations, which are limited only by the necessity of the elements or contrary forces, and by fatality; *chance becomes the generator of all.* Now, in organized nature there reigns, on the contrary, a constantly normal and regular series of productions. Order and intelligence predominate every where, even in anomalous or monstrous formations. Although the more exact observation of the moderns by means of the microscope has greatly restricted the number of these pretended spontaneous productions, whether among the intestinal worms and other epizoa, or in the class of infusorial animalcula; although we have already shown the existence of sexes in certain genera and a propagation, whether by very small ovules, or by fissures or suckers, as in a multitude of vegetables, it would perhaps be rash to deny altogether the possibility of spontaneous generation in these inferior beings. It has been asserted that there is a *continual creation and a tendency of matter to organisation* every where going on (as the Zoosperms) in the tissues or structures of living beings capable of elaborating them. But these supposed spontaneous animalcules cease to be irregular and orderless in their structure, they assume a *normal shape*, capable of classification; they have their *types*, their *special germs*, very different from the crystalline structure of the mineral. In fact, an organized being is such only by its *entire unity*, binding together its parts so as to confer on it a spontaneousness of action, whether instinctive or voluntary, and a *centre of activity to rule over the entire being.* Life appears only compatible with the emanation and transmission of a *primordial germ in a special form, with organs predestined for a certain end.* Now, these organs manifest themselves in the beings of so called spontaneous creation (the infusoria, the vorticella, intestinal worms, &c.) How then, can they be the work of chance or of some blind power? What has conceived their object, directed their destination, or adapted their structure? The intervention of a creating intelligence becomes then indispensable in all organized vitality. It is a mysterious incarnation, inexplicable by the means within our limited reach. *Life, organization,* as shown upon this globe, are in their attributes and origin the most convincing evidence of an intellectual power in the animal and vegetable kingdom, or the direct emanation of a divinity, of which humanity is the term.

From these considerations, says M. Virey, the hypothesis of pantheism or of the *unity of substance* appears to be perfectly inadmissable.

Researches upon the Development of Bone.—By M. FLOURENS.—*Importance of the Medullary Membrane, or Internal Periosteum in the Formation of Bone.*—M. Flourens states, that in his previous works he has considered the medullary membrane, or internal periosteum only as the organ of the re-absorption of bone; it is, however, also an organ of formation to the bone. In a recent experiment, he removed the entire external periosteum from the tibia of a duck, and the whole of this outer membrane was reproduced. But before this re-production took place, the normal for-

mative action of the internal periosteum became increased, and fresh bone was formed in the interior of the medullary canal. Independently of its power of re-absorption, the internal periosteum has then a power of formation, which becomes especially apparent when the external periosteum is destroyed. When this destruction is performed over the whole extent of the bone, new bone is formed throughout the entire interior of the medullary canal; when on the contrary, the external periosteum is removed but from a portion of the bone, new ossific matter is thrown out only at the corresponding point of the interior of the canal. Hence, the destruction of the external periosteum is always followed by obliteration of the medullary canal in consequence of a new osseous production, and, on the other hand, the obliterated points of the canal always correspond in position to the site of the removed external periosteum. Two agents concur then in the formation of bone; the external, as well as the internal periosteum. In the normal or ordinary state, each of these agents or powers preserves its proper limits; the external periosteum is constantly producing or repairing the outer portion of the bone, and the internal periosteum—the internal or spongy tissue of the bone. There is, in the natural state, a sort of counter-balancing between these two powers. But if we destroy the internal periosteum, the power and action of the external membrane become augmented, and new bone is produced externally to the old one; and *vice versa*.

Experiments upon the Increase in Thickness of Bone.—M. Flourens states that it has previously been proved by experiments with madder, that the increase in thickness of bone is accomplished by layers placed successively one upon the other. He has recently performed still more decisive experiments on this subject. In imitation of Duhamel, he has encircled with platinum-wire various long bones in different animals, dogs, rabbits, and guinea-pigs. In a young rabbit, he first encircled the tibia with a platinum-wire, placed immediately upon the periosteum; the animal was allowed to live twenty-eight days before killing it. The ring of platinum wire was found near the middle of the bone, encircling in some points what remained of the old periosteum, and in other parts it was itself covered by the new periosteum. We see, then, first, that the new periosteum is formed above the old. A second rabbit, experimented on the same day as the preceding one, was not killed till the thirty-eighth day after the operation. In this case, the platinum-ring was not only covered entirely by the periosteum, but it was also, for a certain extent, covered with a layer of bone. Thus the new bone, which had become developed since the application of the ring, was formed above the platinum; that is to say, in external layers placed one above the other. So also with a third rabbit killed a few days later. These experiments, he thinks, are conclusive. The only objection was one suggested by Duhamel, who, after performing similar experiments, and finding that the ring which at first encircled the bone, was afterwards covered by the new formation, supposed that the fibres of the bone while spreading had become ruptured opposite the ring, and had afterwards re-united. M. Flourens exhibited several preparations, in which the bone remained perfectly smooth and shining, without any sign of rupture, at the points still encircled by the ring; and where the ring was itself covered by osseous layers, the bone was seen to be of new formation. From various experiments, he concludes, that the bone does not distend itself, and become ruptured, but that all new bone is formed above the old. In a guinea-pig, the tibia was encircled with a platinum-wire. The tibia of the opposite side was amputated at the same time. The animal survived twelve days after the operation, and was during the whole time fed on madder. A ring or circular enlargement was found near the middle of the bone formed by new bony matter, and from the head of the bone as far as this ring, the colour was perfectly red. Just beneath this enlargement was found the platinum-wire. Lastly, six or eight *millimetres* below the wire the bone was broken so as to exhibit its original structure, which was of a pure white. In this preparation the new bone was perfectly distinct from the old. The new was entirely red, the old white. All the new bone was above the wire, the old was below it. Lastly, the old bone was exactly of the same diameter as that of the opposite leg, which had been removed on the day that the platinum was applied. Bone is then formed by successive layers, placed one externally to the other.

Experiments upon the Increase in Length of Bone.—In imitation of the experiments of Duhamel and J. Hunter, M. Flourens bored two holes in the tibiæ of several rabbits. The space between these holes was measured very exactly. The tibia of the opposite leg was at the same time removed and kept for the purpose of comparison. In one animal which had lived twenty-eight days after the experiment, the interval between the two holes remained the same, although the animal had sensibly enlarged; the tibia in particular had increased twelve *millimetres* in length. Upon other animals killed, the one fifty and the other eighty-seven days after the experiment, the same results were obtained. The bone then elongates itself only by its extremities; it increases in length by terminal layers placed in *juxta-position*.

Mechanism of the Reproduction of the Periosteum.—The periosteum is re-produced by external layers placed one above the other. The before mentioned experiments, performed with the platinum-wire passed around the periosteum, abundantly prove it. In these experiments, the ring is placed above the periosteum, and we may still see the old periosteum beneath the ring, while a new membrane is already formed above the platinum, and covers it over.

SILK HATS AND BALDNESS.

Few people are aware of the evil consequences which may arise from constantly wearing a silk hat; they, indeed, may be sensible of the effects, but the cause remains hidden from them. They are, says the "Chemist," thus manufactured. A body is made of pasteboard, willow, canvass, cane, Mackintosh, or stuff of the proper shape of the hat. Over the body is laid a strong varnish, principally composed of resin, linseed oil, and the commonest, as being the cheapest, naphtha that can be procured, to which silk hats owe their highly offensive, and, we believe, very unwholesome odour, by means of which the silk plush is made to adhere, and by which they are rendered air-tight. The silk cannot be introduced into the body by the same means as the beaver is. It will be perceived that the fur is introduced into the very substance of the body in such a manner as to have the appearance of having grown there, while the silk plush is laid on by means of a thick, glutinous varnish. To these differences are to be attributed the ill effects of which we are now about to speak. It has long been observed, as is well known to the trade, that silk hats keep the head much warmer in summer, and much colder in winter, than beaver hats do, owing to the much greater impermeability of the former, caused by the layer of strong varnish above spoken of. This varnish, stopping ventilation, prevents the passing away of the warm vapour arising from the head while in a state of perspiration, causing it to condense again on the hair, sometimes covering it with large drops. Thus, at a time when ventilation is carried in other things to a prodigious extent under the superintendence of Dr. Reid, the head is kept most prejudicially free from its beneficial effects.

Medical men are well aware of the importance of getting rid of the excretions, and will concur with us in saying that this effect of silk hats must be a highly injurious one, as, indeed, the facts which we shall adduce sufficiently prove it to be.

Men who constantly wear silk hats lose their hair much sooner than those who adhere to the use of beaver; and this will explain to many, who have not before been able to account for it, the reason of their becoming permanently bald, and not unfrequently experiencing very unpleasant sensations about the head. The fact that those who wear silk hats become bald earlier than others is well known to every one in the hat trade. A traveller for a large firm has been heard to say that he would eat every hair left on the head of a man who had worn a silk hat for ten years; meaning, of course, that such a person would be completely bald.

It may not be out of place to mention here, that a manufacturer who makes very large quantities of the silk plush for hats, being desirous of patronising an article from which he derived considerable emolument, ordered a silk hat, and wore it for some time. He experienced very great uneasiness about the head, and, at the advice of a friend to whom he mentioned the circumstance, he left off the silk hat, returned to the use of a beaver hat, and suffered no further inconvenience.

DALBY'S CARMINATIVE.

R. Tr. Opii. ʒj.; Tr. Assafet. ʒiiss.; Olei Carui. ʒj.; Olei Menth. Pip. ʒij.; Tr. Castorei, ʒviss.; Sp. Rectif. ʒvj.—M. S. A.

When the mixture is complete, it is to be divided into two-drachm doses, which are to be poured into small bottles containing from seven and a half to ten drachms a-piece, into each of which a drachm of calcined magnesia has been previously introduced. Finally, the bottles are to be filled up with simple syrup, and a small quantity of rectified spirits, and to be well shaken to mix the whole.

This medicine is one of the most ancient and popular arcana in Great Britain, where it is recommended in the flatulence, gripes, convulsions, &c. of infants; and in the irregular gout, the bloody flux, and violent cholic of adults. It is thought eminently serviceable in the different bowel complaints to which sea-faring men are very subject.

Five or six drops are given to weakly infants two or three days old, in a tea-spoonful of warm water sweetened; and if this dose does not produce the desired effect in six or eight minutes, it is repeated. The dose is augmented in proportion to the age of the little patients, and the severity of the symptoms to be combated. Two doses in a day, or three at the most, are sufficient for the most obstinate cases.

A tea-spoonful is given to infants from one or two years old, or even more if the symptoms are violent. Three tea-spoonfuls are given to children seven years old.

Adults take half or two-thirds of a bottle for a dose, either pure, or mixed with as much warm water as will make it of an agreeable temperature. In all cases it is necessary to shake the bottle before pouring out the dose.

It has been observed that in persons subject to constipation, or who vomit acid matter, it is very useful to combine magnesia with the use of this carminative.

Like other popular nostrums, adds a contemporary, Dalby's Carminative is made after various

receipts, so that the dose which is perfectly safe when the cordial is prepared by A, may be poisonous when it is manufactured by B. In the Returns from the Coroners of England and Wales, made to the House of Commons in 1839, we find ten cases of death from Godfrey's Cordial, and one from Infant's Mixture. Dr. John Clarke mentions an infant destroyed by forty drops of Dalby's Carminative.

TO CORRESPONDENTS.

C. ... is ... attended to in the brochure. *It came too late for the number.*

Declined.—*Donatus—Walter C.—L. L.—A B.—M. D.—Mr. H. Topsham.*

We shall next week give an abstract of the Act regulating the payment of Medical Witnesses, and thus answer at once a host of enquiries we have received on this subject.

Several Correspondents are entitled to our acknowledgments.

The Medical Times Almanac.—*As we take it for granted that all our immediate subscribers will be anxious for a copy of our Almanac, which for fourpence plain, and fivepence stamped, will really give a guinea's worth of solid information, we shall, to save them the expense of writing for it, send a copy with every number that leaves our office. Our other friends are requested to give their orders to their newsmen and booksellers.*

NOTICE.

ON THE 1st OF DECEMBER NEXT, WILL BE PUBLISHED, AS AN APPENDIX TO OUR ORDINARY NUMBER, A **MEDICAL ALMANAC**, REPLETE WITH MATTER THE MOST VALUABLE AND INTERESTING FOR THE MEDICAL PROFESSION.—IT WILL CONSIST OF 72 QUARTO COLUMNS.—Price 4*d.* Plain, 5*d.* Stamped.

Errata.—In Mr. Adam's "Case of Clairvoyance, in our last No., in 2d column, the 26th, 27th, and 28th lines are misplaced—in 3d column, line 81, read "*low*," for "*being*,"—in 4th column, line 37th, for "*moral*," read "*excite*."

THE MEDICAL TIMES.

Saturday, November 26, 1842.

Currere per totum pavidi conclave, magisque
Exanimes trepidare, simul domus alta Molossis
Personuit canibus. Tum rusticus, &c.

Horace.

If "le diable boiteux" continue to take an interest in human perplexities and embroilments, he must enjoy a more than customary treat, while, hovering over the council chamber of the College of Surgeons, he surveys the condition to which the question of practitioner-examination has reduced the embarrassed twenty-one. The explicit letter of their late President being now in every practitioner's hand, and Dr. Hasting's avowal of its receipt for wide publication being by this time no less known, the secretary of the College is dunned each post by bagfulls of letters he dare not answer; the doors are besieged by clamorous thousands, who will not have promises made to the ear broken by any miserable word-jugglery to the hope, and there they sit—these select chieftains of an enlightened profession—each ill at ease with his neighbour, and scarcely less so to himself,—mutual dislike in its increasing intensity overcoming their power over the sad ceremony of their usual smile: all (save the sleek, fat, Cæsar-loving Anthony) hating and hoping, and fearing and distrusting, and fuming and frowning, and threatening—each conscious of bearing his share of corporate ridicule and embarrassment,—the majority internally asking with bated breath and humble reverence, what *are* our laws, and what our regulations? what means are there of knowing what we have done, and what not? what *is* the College of which we are called the heads? by whom is it managed? how, when, and where?—and nearly each feeling that somehow the machine has gone on without HIM! But their mutual vexations will not relieve them from their ludicrous embarassment: a decision must be come to on an important question which they themselves have raised, and, despite the contempt it may fling on their authority, that decision *must be* against themselves and their certificate system, and in favour of those to whose expectations they have in one way or another directly given origin.

How stand the facts of the case? About April last, by no small exertions, to which the president (at that time) of the College largely and, as he said, most successfully contributed, the Poor Law Commissioners introduced various changes in reference to the medical officerships of unions,—one of which was the exaction from all candidates for such posts, of a diploma, not only from a medical, but an *English surgical* source. It being immediately felt that this arrangement would exclude many *competent* practitioners, good, and even *examined* surgeons from situations which they had long held, or looked forward to,—it was suggested first, and among public journals *solely*, by ourselves, that the English College should give such gentlemen an opportunity of proving whether they possessed (without reference to certificates) such practical surgical knowledge, as would at once give them a fair title to membership in that institution, and a just claim to compete for a surgeonship in the public service. The Court of Examiners appear to have thought as we did; for in July they *were*, and for some time previously *had been*, admitting practitioners to examination on their merits practically, and without reference to the customary rules and regulations. *This is a fact*, not to be gainsaid; it is attested by a public document, and signed by the very best of authorities—the then president of the College, who shewed a great and very praiseworthy anxiety to have the fact made as publicly known as possible. Did the College, in thus admitting such practitioners, do so on public or private grounds? To say private grounds would be to convict it of the worst kind of misrule a public body is capable of; if on public grounds, what shall justify its non-extension of the same right now to individuals in precisely similar circumstances? We ask the question, and dare the College to give us the pretence of a reply.

The explanation, however, of all the recent fuss made by some worthy members of the council on this matter, is precisely this. So long as the admission of old practitioners could be made a subject of personal favour by the Court, and thus turned into means of increasing influence—not to say practice,—so long was the innovation patiently acquiesced in; but the moment that Mr. Guthrie's frank letter turned it from a vehicle of favouritism into a matter of general right and universal claim, that moment is a shew of resistance exhibited—a resistance, be it remarked, which, presenting the council as ignorant of their own minds individually and collectively, as without concert, harmony, or the least pretence of decent consistency or justice, makes them odious to one part of the profession and contemptible to the other! But to suppose, we repeat, that there will be more than a show of resistance would prove a sad suspiciousness on one side, or silly unprincipledness on the other; for it would suppose the twenty-one registering themselves not only as a most lawless and illegitimately governed set, but as men who with the solemn charge of protecting our Profession, sacrificed the happiness of a large portion of its members — not for private interest, which would be something, but for private whim and spite!

An humble contemporary—the "Gazette" of Wits' Bankrupts—lately contradicted our rumour (as it called it) on this subject, on what it declared "high authority." "*High* authority" varies in its meaning, according as the utterer recedes or approaches this or that level, and as our private correspondence suggests that such a contradiction was in fact ventured on, the day before the Gazette appeared, by *the porter of the College*, we are not disposed to dispute that, in the editor's opinion, his *assurance* was founded on "*high* authority;" certainly it was *high* enough to be far, very far *above* the truth. Clearly the College has been in the habit of making such admissions, and clearly the President in the most perspicuous language made such admissions a matter of universal claim to all practitioners in need of them. Our contemporary's authority therefore, however "high" physically, or relatively to the genteel editor himself, must be extremely "low" in the moral aspects of veracity and respectability. Of all liars, save us from the daring power of assertion of your *official liar*. From the Moniteur downwards there is no fact outside, aye or inside mathematics, though attested by a whole nation of witnesses, which one of these *hopeful* gentlemen will not coolly contradict on "the highest authority." If there be one character lower than this, it is the writer, who, in a silly desire to be *mistaken* for official, volunteers uninvited to do the same dirty work gratis!

To finish with something more useful than fly-crushing, there are two duties which cannot, we beg to impress on the Council of the College, be performed too soon. First, to let students know decisively whether they can or cannot be examined under the old regulation after January next; and secondly, as it is clear that practitioners are admissible by examination on their me-

rits practically, to make known how long this privilege is to lie open for their acceptance. On both points it belongs to the duty of a governing professional body to allow no mystery or misunderstanding. Inconvenience, embarrassment, perplexity, and loss, are a few of the necessary consequences of the doubts on these matters that now universally prevail. Apart from this, it is not seemly that no two members of the council can agree on what are, or what are not the regulations or intentions of the College. What Stanley, with lucky truth, declares nonsense, Guthrie, with equal veracity, calls a college practice; what the latter declares contemptible, the former insists on as a legitimate law. The other councellors shew a similar harmonious agreement; and their worthy secretary, when he ventures to rise above ignorance on any given subject of enquiry, is found to be at variance with all. This is *not* respectable; it exhibits that worst anomaly —a governing body ungoverned.

MESMERISM.

A CASE OF AMPUTATION DURING MESMERIC SLEEP.

On Tuesday evening a paper was read at the Medico Chirurgical Society, at their rooms in Berners-street, the joint production of Mr. Topham, a barrister, and Mr. Squires Ward, the surgeon, relative to amputation of the thigh during mesmeric sleep, at the district hospital of Nottingham. There was an unusual attendance of fellows, and visitors, and the crowd was so great that many were compelled to stand during the reading and discussion of the paper. Among the visitors announced from the chair were, Colonel Gurwood, Captain Valliant, Dr. Walsh, Dr. Binns, Mr. Denison, M.P., Dr. Allnutt, Dr. K. Grant, &c.; and, subsequently, the Marquis of Litchfield was introduced by Dr. Elliotson. Among the fellows present we noticed, Dr. James Johnson, Dr. Arnott, Sir James Clark, Dr. Marshall Hall, Dr. Elliotson, Dr. Syme, Dr. Bell, Dr. Moore, Dr. Williams, Dr. Forbes, Sir Benjamin Brodie, Mr. Liston, Mr. Bransby Cooper, Mr. Coulson, Mr. Alcock, &c. &c., and, in short, nearly every man of eminence or consideration in the profession in London.—The preliminary business of the Society having been concluded, the paper was read by the secretary. The first part, which was written by Mr. Topham, professed to propound no theory, but to detail facts; and went on to state that the patient, James Wombwell, an agricultural labourer, was first seen by him (the author) on the 21st of June last (we believe this was the date),—that he was then suffering great agony from an affection of the knee, which subsequently proved to be inflammation and absorption of the ligaments, with caries of the condyles of the femur and tibia,—that, after repeated attempts to mesmerise him, he fully succeeded—and that at length, in September last, he was thrown into mesmeric trance, when the operation of removing the thigh was performed by Mr. Squires Ward. To secure deeper sleep than usual, Mr. Topham placed his thumbs, or fingers, we forget which, on the balls of the eyes, and kept them there during the operation, the patient during the whole period of the process sleeping soundly, and only making a low moaning like that of a man in a troubled dream, when the bone was sawed. On being asked by Mr. Topham, after the operation, if he felt any pain while in the mesmeric trance, he replied, "No," but that he heard at one time something like "a crunching,"—this was when the bone was sawed. The second portion of the paper was strictly surgical; Mr. Ward describing very minutely the symptoms of the case, the previous treatment, the operation, and subsequent recovery of the patient; but as these points offer nothing remarkable—except that, from the position of the patient, he was compelled to make a third incision, which, in ordinary cases, would have caused increased pain, but, in this, did not affect the patient, and that the sciatic nerve was irritated without inducing pain,—we shall pass on to the discussion, which, we are bound to say, was conducted with more candour and moderation than we have generally generally among our medical brethren. We hail this as a good sign. Whatever may be said of the intolerance and illiberality of the profession, the time is passed when any professional man, however high in public estimation, dare attempt to check inquiry, or prevent discussion.

Mr. Coulson was the first to express an opinion to the effect that he regretted the reading of the paper,—we could not understand his reason.

Dr. Moore then wished that the paper had been accompanied by affidavits, as a paper like that required such documents.

Mr. Wood said, if any testimony were requisite, he begged to state that he assisted at the operation (we believe both Mr. Ward and Mr. Topham were present also), and that there were clergymen, laymen, and other surgeons, present; and, consequently, nothing could be easier than the production of such a document, if Dr. Moore insisted upon it—but for his part he saw no necessity for it.

Mr. Alcock was of opinion that the question was not, whether no sense of pain was expressed, but whether any pain was *felt*. He had performed many operations, and some patients—one even smoked his pipe during the operation—expressed little or no sense of pain. He was not, therefore, satisfied that the patient did *not* feel pain, though he did not express any.

Sir B. Brodie followed on the same side. He quoted the case of the sleeping boy, related by Dr. Oliver, of Bath, in the Phil. Trans., who suffered pins to be thrust under his finger-nails, was cupped, and otherwise tortured, without shewing any sign of pain. Sir Thomas Hardy, he said, scarcely knew what pain was; and he had himself, in performing an operation for femoral hernia, on a very illustrious individual, observed his total indifference, taking up the different instruments and examining them, and putting questions to him as to the progress of the operation, until he touched a branch of the ischiatic nerve, when he exclaimed, "You hurt me." He instanced some other cases, but we could not see in what way they bore upon that before the Society. He concurred, he said, with one of the gentlemen who had spoken, that this paper should not have been received by the council, or permitted to be read, as he himself was perfectly satisfied with the report of the French academy, and considered mesmerism a complete delusion.

Dr. Blake offered a few observations to the effect that a girl, named Ross, in the North London Hospital, had simulated mesmeric phenomena, and had subsequently admitted that she had simulated; and supposed this case was similar.

Mr. Bransby Cooper wished that some of the mesmerisers would tell the Society how its effects were produced, and what was its *modus operandi*?

Mr. Liston hoped the mesmerisers would tell them, also, something about people reading with their bellies and elbows (*ipsissima verba*.)

Dr. Syme explained, and said he had witnessed several cases of persons, in mesmeric trance, reading without using their visual apparatus.

Dr. Mayo was of opinion that there was something more than mere imagination, or indifference to pain, during the presence of what was called, mesmeric phenomena. He had, himself, thrust a pin, nearly up to the head, in the arm of the girl, Elizabeth Okey, when she could not have had the slightest knowledge of his intention, yet she evinced no pain. He then cited the case of Jules Cloquet, in which he removed a cancerous mamma during the mesmeric trance, without the patient feeling any pain. He was of opinion that there was something more in these phenomena than could be referred either to imagination or to stoicism.

Dr. Arnott seemed to argue that the evidence was inconclusive, because he was present at a case where, after fifty ounces of blood had been taken from the patient, she fainted, when a tumour was removed near the orbit of the eye, without her perceiving any pain. He thought the evidence inconclusive, but wished for further investigation.

Dr. James Johnson referred the whole to imagination, or stoicism. He was bound to believe the testimony of the gentlemen who had brought forward the case; but he would frankly add, *that he would not have believed it, had he seen it himself.*

Dr. Marshall Hall contended that the patient *must* have felt, or the other leg would have been convulsed.

After a few remarks from Captain Valliant, in which he described the operation performed upon his servant, in May last, by Dr. Charlton, of Chatham,* while she was in the mesmeric trance, without her being aware of it,

Dr. Elliotson explained, at some length, his views of the subject. He said he could not see the analogy between the cases cited by Sir B. Brodie, and that before the Society. In Sir Benjamin Brodie's case—the patient expressed suffering when the nerve was touched, whereas, in the present case, the nerve was irritated by the probe, yet the patient evinced no sign of suffering! Cases of insensibility to pain were not uncommon. There was a case reported in the *Lancet* for 1839, of a patient in the Edinburgh Infirmary, out of whose hands an attendant had actually *dug, with his nail*, portions of flesh while in an insensible state, without her feeling it,—but he did not see how it bore upon this case. In conclusion, the doctor said, that he was not satisfied with the report of the French Academy, and that he preferred nature for a guide. He was convinced of the truth and reality of the mesmeric phenomena, and should persevere, as he had hitherto done, in his researches in mesmerism in spite of ridicule, or whatever other weapons, might be brought against it or him.

The President (Dr. Williams) very briefly addressed the meeting, stating the reasons why the Council had brought forward the paper; and asserted that they were right, from the number of persons he at that moment saw before him. Prolonging the debate, however, any longer, might, in the eyes of those who blamed the Council, be only increasing the evil. He, therefore, would put a stop to it.

CASES OF PERITONEAL SECTION

FOR THE EXTIRPATION OF DISEASED OVARIA BY THE LARGE INCISION FROM STERNUM TO PUBES, SUCCESSFULLY TREATED, WITH OTHER CASES OF EXTIRPATION OF ANOMALOUS TUMOURS, &c. &c.

By CHARLES CLAY, Member of the Royal College of Physicians, London, of the College of Surgeons, Edinburgh, and Lecturer on Medical Jurisprudence, &c. Piccadilly, Manchester.

(Continued from page 100.)

CASE THE THIRD.

I was consulted by Mrs. Dillon, who had been labouring for many years under an enormous enlargement of the abdominal regions. Hard to the touch without fluctuation, on testing it by percussion (except a little on the left side) the integuments appeared to be slightly moveable on the surface of the tumour, which, however, was so extremely large and filling so completely the abdominal cavity, with the smallest perceivable quantity of ascitic deposit, that I could not expect to find much mobility in the tumour, or of the integuments over it. She was in her forty-seventh year, still menstruating, never had any children, and had been married eight years; the tumour occupied more of the left, than the right side; she had a fall from a window about nine years ago, when she struck the left hip against the floor, but did not perceive anything remarkable for nearly two years after, when a tumour the size of a goose-egg appeared in the left iliac region, which did not appear to increase much till

* This case was reported in No. 144, Vol. 6.

about four years ago, from which, to the present, it had increased rapidly; she was now forty-five inches in circumference at the umbilical region, and at a rough guess, the tumour might probably weigh thirty-five pounds. She was subject to frequent very severe pains in her back and iliac regions, and had tried every means of relief proposed; about two years previously she was tapped, but only two pints of thick bloody fluid were extracted, affording her no relief; the solidity of the tumour appeared to offer no hope from tapping. In spite of every means tried by many excellent practitioners, she rapidly progressed for the worse, her life was truly miserable, and she was pressingly anxious to adopt any means, however slight the chance of success; convinced, that at most, her life under present circumstances could be but very short, and almost unbearable, she concluded an operation would only terminate it a few days sooner, if it did not succeed; she had been long unable to partake of solid food, and had often great difficulty in voiding urine; under these circumstances, she earnestly entreated me to attempt relief by operation, and from the success of previous cases, her anxiety for its adoption was extreme. In vain I argued that her case had not the same prospect of success as the others preceding her's, and that if it was performed, the chances were greatly against her; her importunities at length prevailed, and I somewhat reluctantly consented to operate. It was therefore decided to be on the 26th of October, at which time I was met by my friends Drs. Radford and Black, Mr. C. W. Vaudrey, Mr. G. Southam, Mr. Middleton, Mr. Holroyd, Mr. J. J. Southam, surgeons, and Mr. Winterbottom, a pupil. It was agreed by all present, that the case was not a promising one, and could only be justified by her importunities and miserable state of existence; at the time of operation too, the catamenia appeared, which might have afforded means of putting off the operation, but she informed me whilst undressing, she should suffer more from depression by the delay

OPERATION.

A bold incision was made, as in the previous cases, which was no sooner done than it was evident to every one present that to remove the mass was quite impracticable, the whole anterior surface of the tumour was adherent to the peritoneum, so much so, that there was not room in any place (except immediately above the pubis) for the flat end of the scalpel handle to enter between the peritoneum; in addition to this, the character of the tumour was evidently of a very different character to the generality of ovarian tumours; it appeared highly vascular, and though laid bare, we could not discover in it any fluctuation on percussion: a brief consultation was then held, when it was decided to make an attempt to lessen the tumour, if possible, before bringing the integuments together again, in which some difficulty was apprehended from its tenseness.

The tumour was pierced in various places with a fine stiletto, when a jet of pure blood issued from each puncture; from this it was evident all attempts to lessen the tumour were useless, and I was reluctantly compelled to close the external wound without affording any effectual relief; the integuments were then brought together as usual, but using more sutures, as the mass beneath rendered it necessary; the parts were well secured by plaisters and bandages, and she was put to bed much depressed in her mind from the fact of its not being removed. One grain of mur morphine was given her. Pulse low and feeble.

At the termination of the fourth day that is, four o'clock P.M. on Sunday the 30th, the wound was examined, and was found adherent nearly its whole length, except about two or three inches just immediately above the pubes where adhesion had not taken place; some of the straps were removed, but no sutures cut out, and all the parts being well cleaned, the bandages were re-applied, during which, she felt little or no fatigue.

Monday morning eight o'clock, A.M.—Found her very comfortable, had slept moderately through the night, voided urine easily, had a motion, felt little or no pain except a kind of smarting along the wound. The husband requested to be allowed to give her a little gin-and-water, as she had been accustomed to take it for the wind with a clove of garlick. I distinctly told him the disastrous consequences that might follow such an attempt, and that on no account whatever must he for a single moment indulge in such an idea; on leaving the room, one of the females attending stated, that she had had much difficulty in dissuading him from giving it to her. Up to this time, the fifth day after the operation, the case had progressed as satisfactorily as could be expected, and even more so, when the nature of the case was considered; viz., an enormous malignant fungoid tumour, at least thirty pounds in weight, distending the abdominal parietes; secondly, the depressed state of the mind arising from the inability to remove the tumour, with the certain prospect of death very shortly, even though the wound might heal; these circumstances led her to indulge the wish to die rather than live. With all these disadvantages she had done well.

Monday evening four o'Clock being the termination of the fifth day, I was hastily summoned in consequence of a swelling accompanied with pain of the left leg, from the toes to the middle of the thigh, the pulse quick, feeble, and thready, still the tongue and general surface was moist and warm; no thirst; and had slept some hours during the day, as well as taken a fair portion of her simple food. It was impossible to reflect on the progress of the case as above stated, the sudden change for the worse without any premonitory symptoms, and the peculiar character of the present appearances, without suspecting some interference of the most unwarrantable description in the nursing, particularly when coupled with the wish to exhibit stimulants in the morning of that day. I did not hesitate in challenging her husband with the matter; he, as well as the attendants, denied having given her any of the gin, but neither so positively, nor so free from hesitation and confusion as to lead me to credit their statements. The leg had much the appearance of a case of phlegmasia dolens. Warm emollient fomentations were applied, and some relief from pain derived from them; the pulse, however, rapidly fell to indistinctness, and she expired in less than twelve hours from this inflammatory attack on the morning of the sixth day.

CONCLUDING OBSERVATIONS.

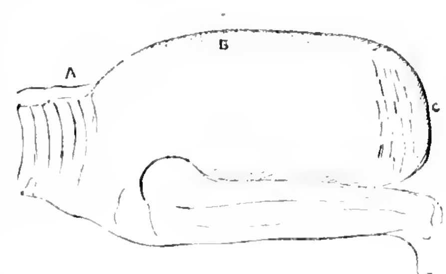
I now earnestly directed my efforts to obtain an inspection of the body; but this the husband very determinedly opposed; indeed, I fancied he imagined I should be able to detect what I had just reasons for suspecting, and what I learned two or three days after to be the fact, viz, that gin with garlick had been administered under an impression of expelling wind from the stomach. Unfortunately as this case terminated through the unwarrantable interference of the husband, against which he had been earnestly cautioned, yet it in no way disproves the legitimate principles of the operation. It will be impossible for any impartial person to scan over the record of this case without acknowledging, that with all the immense disadvantages of the case, there was every reason to hope a more favourable issue from the rapid and satisfactory progress it had made till within twelve hours of death. The case too, lived sufficiently long to prove the peritoneal section comparatively safe; the wound had in a great measure healed, and all the dreaded circumstances connected with an operation of such magnitude had in a great measure disappeared, and though the case must have soon terminated fatally of its own accord, yet I feel confident the progress of the first few days was so satisfactory, that had justice been done, the case might have lived for some time; *as it was, the case was decidedly successful as regards the effects of the wound and abdominal exposure.*

CASE THE FOURTH.

When I commenced the record of Mrs. Wheeler's case of peritoneal section, I had no thought of being so soon engaged in a second of the same nature; that, however, has taken place, and more successfully, if *possible*, than the first: such results naturally increase my opportunities. I have now a fourth case to record, with a prospect, at this moment, of at least four or five more. It is my intention to persevere in this operation until I have produced sufficient evidence to establish a legitimate operation of British (as it is already of Foreign) surgery, or until I discover enough to condemn it. In accomplishing this, I shall find much greater difficulty in overcoming the feeling of reluctance generally manifested by the profession towards any new and bold step (though supported by numerous proofs), than I should in meeting with condemnation for the unfortunate result of some one or two isolated cases, which in no way affects the principle of the operation, but affords arguments to those who are prejudiced against its being adopted as a legitimate means of relief. In this, however, I am not singular: Harvey met with the most virulent opposition for many years, to doctrines since acknowledged to be founded on truth. Jenner's discoveries were as strongly opposed, and as firmly admitted, subsequently. Cullen's views were attempted to be driven out of the pale of the professional enquirer by the numerous followers of Brown. For stepping beyond his colleagues, Liston had to seek shelter under other than his native skies. And, lastly, the very operation which I have had the honour to introduce to English surgery was used as a means to cry down the talents of that eminent surgeon, Lizars of Edinburgh; and the advocacy of similar means by the talented Blundell, brought the battery of the illiberal part of the profession against him. This is not a healthy condition of medical society in the British dominions. The vaunted liberality of the medical profession, from Hippocrates down to the present day, is more a matter of history and conjecture than reality. Men practising the profession, not content with the limited views just enough to enable them to make a living by their exertions, but putting forth their energies and endeavouring to improve the principles and practice of the science may, and ought to expect the envy of their professional brethren; but this should be entirely apart from an illiberal and uncharitable expression of feeling. In this our continental brethren are our superiors; the spirit of emulation is more generally encouraged; and the spirit of detraction less practised by them, combining together rather to assist the advancement of science than throw obstacles in the way of such advancement. These remarks may appear uncalled for; but this illiberality has already put forth its ugly head, in respect to myself: and it is necessary to apprise the professors of such principles, that every man who has the love of his profession at heart, looks upon them only as *incapables* or "*stand-stills*," as Dr. Blundell justly called them, "Men whose opinions will never reach posterity."

CASE of Hannah Edge.

Early History.—Hannah Edge, of Thornset, near New Mills, in Derbyshire, arrived in Manchester by coach from the former place on Wednesday the 2nd of November 1842, to consult me on her very remarkable case; and certainly, I was no little surprised at her appearance; she had the abdomen enormously enlarged, the umbilicus almost touching the knees. The following sketch will give some idea of this singular case:—



A, *the Sternum.*

B, *the Umbilicus.*

C, *Pendulous part of the Abdomen.*

From Sternum to Pubes, 38 *inches.*

Circumference at Umbilicus 51 *inches.*

When she sat on a chair she formed an inclined plane; and when she attempted to walk, the head and shoulders had to be pitched backwards to a very considerable degree, to maintain the centre of gravity, and her arms were used as balancing poles, after the manner of a tight rope dancer; the whole appearance was remarkable, and could only be exceeded by the singular ovarian case of tapping recorded in the MEDICAL TIMES, of October 1st. 1842, By S. S. Brame of Lowestoft, in Suffolk. Her age was 39, tall and emaciated; her health, however, had been generally good, and her family was also healthy; she had had three children. About seven years ago, immediately after the birth of the second child, she discovered a considerable enlargement of the lower part of the belly on the right side, about the size of a person four month's advanced in pregnancy; not feeling any particular uneasiness she did not take any medicine for it. Four years ago she was confined of her third child; she was very large at her confinement, and afterwards nearly as large as a person at the full period of pregnancy. She thinks the tumour might have existed before the birth of the second child, but did not notice it. After the birth of the third, she applied to different persons for relief, but medicine appeared to have no effect. She had been tapped four times; first time in two places, when twenty

pounds of fluid were extracted; second time, twenty-four pounds; third time twenty-eight pounds; making in the whole four tappings. She was so enormously large, that I called in my friend, Dr. Radford, to see her, who joined me in the strict investigation of her case. The parietes were extremely thin, and fluctuation felt equal throughout the whole surface; it was concluded to perform paracentesis abdominis on the following day, (November 3). Accordingly Dr. Radford, Mr. J. Southern, and myself, met, when I pierced the parietes on the right side about midway between the crest of the right ilium and the umbilicus; after about thirty pounds of a dark glairy fluid were taken away, when the fluid had ceased to run, a large globular tumour yet remained, the walls of which pressed against the end of the canula. I now placed my patient more on her side, (it must be observed hitherto she had been lying on her back,) and without taking out the canula, I introduced the spear, and pressed it inwards as far as possible; I penetrated the sac, and brought away thirty pounds more of a bright limpid fluid; I considered the first fluid evacuated was collected in the abdominal cavity viz. ascitic, although the character of the fluid was more that from cysts, whilst the latter thirty pounds which were evidently cystic, had quite the ascitic character. Dr. Radford supposed there were two separate cysts, or one large one, with a septem; but as I have seldom observed ovarian cases of long standing without ascitic deposit, I am still inclined to think the first fluid ascitic. She bore the operation of tapping remarkably well, and I felt a strong inclination to proceed with the operation of extirpation, but as the advanced time of the day and bad light interfered, the latter operation was deferred to Friday, (the 4th. of November,) at which time, being isolated from her friends, it was judged proper to defer it until her husband and friends had been sent for, and a statement of the prospects of the case had been made to them. This step was taken in consequence of the appearances which presented themselves after the sixty pounds of fluid had been drawn away. The flaccid integuments in closing the tumefied masses hung down between the legs; in the right iliac region was one tumour about two or three pounds in weight, and in the centre above the pubes another about two pounds weight; these tumours appeared to have a membranous connection with each other; higher up and nearly opposite the umbilicus on the left side, a small tumour appeared, which my medical friends considered another connection of the disease, (for my own part, I considered it more as thickened integumental matter, or some other organic enlargement independent of the ovarian disease,) probably the spleen not enlarged at all, but only rendered more apparent by the flaccid state of the integuments, and a little displaced from the previous distention. My medical friends Dr. Radford, Mr. W. C. Vandrey, Mr. G. Southam, Mr. Nursaw, all considered the adhesions very extensive, (and as there is much latitude for opinion in such obscure cases) I must confess I did not agree with them as to the extent of adhesions. It appeared to me when these gentlemen grasped the integuments that they included the walls of the cyst, which made parts of the tumour appear more adherent than they probably were; I was certain some adhesions did exist, but from observations on other cases, I felt convinced that where there were extensive deposits of water, the adhesions were likely to be of a less serious nature, and more easily separated than if the tumours were of a more solid nature, and I may here mention what appears to be a fact connected with ovarian disease, namely, the size of the solid part of the tumour is in inverse ratio to the quantity of fluid deposited. Thus in Wheeler's case, ascitic deposit seven pounds and a half, tumours eight pounds and a half, cystic deposit eight pounds and a half. Beswick's case, ascitic deposit twenty-five pounds, tumour five pounds, cystic deposit four pounds. In the present case, ascitic deposit thirty pounds, cystic deposit thirty pounds, tumour about three or four pounds. This of course arises from the breaking up of the solid into small, and the smaller into larger cysts. The peculiarities developed by this case fully justified my friends in requesting me to postpone the case, in order to make her friends aware that it was a case of great danger, and though no prospect presented itself for relief otherwise, and a rapid deposition again certain (it being only twelve weeks since she had been tapped before) so that her life would, in all probability, be very short, and accompanied with much incumbrance and misery; still it was the most prudent course not to operate, unless the patient and her relatives after being made aware of the full extent of the danger, were really determined it should be done. To this I reluctantly agreed (I say reluctantly) because it was with no other view she came to Manchester, and I dreaded the delay would create an alarm in her mind that would tell against her in the case when subsequently operated upon. Lastly, I esteemed it of consequence, to let one stage of irritation and inflammation answer for both tapping and extirpation. After this, her friends visited her, when with them she was determined to be operated upon, and accordingly the 8th. November was fixed at 12 o'clock A.M.

(To be continued.)

MEDICAL CHARITIES OF IRELAND.

(From the Dublin Monitor.)

We have just received a copy of the Bill for the Better Support and Regulation of Medical Charities in Ireland, brought in by Lord Eliot. At present we make no comment on its provisions, which put the Medical Charities on a thoroughly different footing from that contemplated by the late Government. We shall merely proceed to give a full account of the clauses, leaving to the profession the discussion of its merits, which to us appear very questionable.

Sections 1, 2—The Lord Lieutenant shall appoint, during his good pleasure, a Board of not less than five or more than seven physicians or surgeons, residing in Ireland, of ten years' standing at the least, to act under such regulations as his Lordship may prescribe, and to meet at such places as he may direct. The acts of the majority to be binding.

Sections, 3, 4, 5, 6—The Board, as soon as conveniently after its formation, shall report on the state of disease, and the number and description of every Medical Institution in the several Poor Law Unions; and shall make a like report every succeeding half year. They shall likewise, when required, report on the extent of Dispensary relief requisite in each Union, the number of Dispensaries which ought to be provided for the sick poor, and the amount of hospital accommodation for persons affected with fever. They are also empowered to make orders for the medical economy and management of these institutions, with the consent of the Lord Lieutenant.

Sections 7, 8, 9—His Lordship shall also appoint inspectors—not to exceed four—who have practised for seven years previous, to inspect under the direction and control of the Board. Their duty shall be to examine into the administration of all Medical Institutions—to ascertain the qualifications of the several officers who conduct them, to require returns of the annual income and expenditure of each institution—the number of patients relieved or treated, and the rules which regulate such institutions. The Poor Law Commissioners are authorised to make regulation orders, and carry the act into execution in all other respects; but their power is dismally interfered with.

Sections 10 to 16—Lord Lieutenant's warrant necessary to validate the orders of the Board and Poor Law Commissioners, both of which are to have official seals. Their general rules to be laid before Parliament. Commissioners may form dispensary and fever hospital districts, and either dissolve or alter them.

Sections 17 to 26—In every district for medical relief, governors shall be appointed. Poor Law Guardians, resident Magistrates, Protestant Rectors and Curates, Catholic Parish Priests, and Dissenting Ministers, as the case may be, to be *ex officio* Governors. When the number of *ex officio* Governors shall fall short of a number for which a blank is left, the rate payers to supply the deficiency who have been rated in the largest sums of money. Donations of £20 to constitute a Governor for life, and a subscription of £2 a Governor for one year. They shall meet at least once a week; but no meeting valid without five being present. No Governor to act except at meeting. Lord Lieutenant may remove them on inquiry.

Sections 27 to 32—Governors to appoint Medical Officers, whose duties the Poor Law Commissioners shall define, as well as the amount of their salaries, which are to be paid out of the poor rates. Medical men removable only by the Lord Lieutenant—non-medical by the Commissioners.

Sections 33 to 39—When any dispensary or fever hospital district is declared, all existing dispensaries and hospitals supported by contribution or Grand Jury grant, to vest in the new Governors; and on vesting, the power of all former, general, and local acts relating to them is to cease. Lord Lieutenant may order Governors to build dispensaries and hospitals, and direct their size and prescribe their plan. He may also order the Poor Law Guardians to furnish dispensaries, and provide all conveniences for the relief of the sick poor. The Grand Juries to present for them in the usual manner.

Sections 40 to 46—Register books for dispensaries and hospitals to be provided by the Commissioners, in which every case of relief shall be entered. Accounts of all expenses to be kept, and estimates of future expenses to be laid before the Board of Guardians every six months.

Sections 47 to 51—No person qualified as Medical Officer who has not obtained a license from the College of Physicians in Ireland, or a degree in medicine of some other College or University in Great Britain or Ireland. No person capable of acting as Apothecary without a license from the Apothecaries' Hall, or the Incorporated Society of Apothecaries in London. Lord Lieutenant may require Medical Officer to be qualified as Physician, Surgeon, and Apothecary, or any two of them, and also to have a certificate in Midwifery.

There is a saving clause for present medical men not duly qualified as Surgeons or Physicians. Such persons shall within three months after the district is declared, obtain a certificate from the Medical Board, of their fitness for the

office, and in default of obtaining it, they cease to be officers.

The remaining clauses, twenty-three in number, are of no public importance, being the usual statute stuffing about the competency of witnesses and certioraris, &c. &c. We have given the fullest analysis we could, and with the exception of the few first provisions, a more lumbering attempt at legislation we have rarely read. In its present shape, "if shape it can be called, which shape hath none," it is wholly unsatisfactory.

DISPROOF OF MR. HALE THOMSON'S ALLEGED SURGICAL IGNORANCE.

To the Editor of the 'Medical Times.'

SIR,—Your paper of November 12th contains some strictures on the professional characters of some of the medical officers of the Westminster Hospital. Among those referred to in that number is Mr. Hale Thomson, and reference is made to an instance of professional ignorance which he displayed in not knowing the os coccygis from the first phalanx of the thumb. An error of this kind would be glaring indeed had it occurred in the manner referred to; but this was not the case. I was a pupil at the Westminster School at the time this circumstance happened, and the true version is as follows.

Mr. Thomson's hour for *reading* his lecture was, if I mistake not, 5 P.M., and he had come into the theatre for the purpose of enlightening the minds of his pupils. the os coccygis lay on the ground, having fallen from the skeleton which hung close to the left of the table. Mr. Thomson saw the bone and picked it up, and scarcely looking at it, carelessly exclaimed, "A phalanx of the thumb, I believe." Now this is an error which might *almost* have been committed by any man, and therefore by Mr. Thomson.

Mr. *Deshon*—not *Deschamp*—did not purposely ask the question, for had this been the case there could have been no excuse for the learned gentleman's mistake; neither would the pupil referred to have simply stated to Mr. Guthrie, *when he met us on the subject of Mr. Thomson's mode of lecturing*, that Mr. Thomson "*did not know the os coccygis from the phalanx of the thumb;*" but would have added the fact alluded to in your number for the 12th of this month, by way of making his arguments for a change of teachers more powerful.

I have taken the liberty of sending you this communication because I love the truth, and if a public character commit a fault, let him have the full benefit of facts and truth; and though Mr. Thomson is no favourite of mine—as a teacher, as a surgeon, or as a private individual,—yet I would be the first to endeavour to do away with any erroneous impression which incorrect statements might produce.

I have the honor to remain, Sir,

Yours, obediently,

AN OLD WESTMINSTER PUPIL.

[This, inserted out of our love of fairness, is certainly *highly satisfactory!* Will Mr. Hale Thomson take a hint given in perfect disinterestedness, and resign a situation which to one with his acute sensibilities must be a constant source of disquiet, chagrin, and self-humiliation? For him assuredly the "post of honour" and even of *profit* is a private station. The pigmy if small on the pavement is smaller still on a column.—ED.]

SPONTANEOUS GENERATION.—M. Mandl has succeeded, by a microscope magnifying 250 diameters, in detecting the coloured eggs of entozoa in the lungs of frogs in which no trace of the entozoa themselves could be discerned. This, he observes, makes it very probable that these little ova, the diameter of which is scarcely more than four times that of the blood-corpuscle of the same animal, have been carried into the lungs either in respiration or by some other passage.

PHRENOLOGICAL SOCIETY.

A MEETING of this Society was held on Monday-evening last, at eight o'clock, in Exeter-hall. The secretary opened the proceedings by exhibiting the casts of two murderers' heads recently obtained. One was that of John Taylor, a farmer, aged 60, executed for the murder of a woman of abandoned character. Previously to his acquaintance with her, his character had been peaceable. Distressed circumstances and ill-treatment from her had led him to commit the deed. Cool Premeditation, Cruelty, Cunning, Amativeness, and Strong Sense of Property, formed the chief characteristics of his phrenological development. The other cast was that of Robert Knorr, aged 30. He had been parted from his wife six or seven times; they had lived very unhappily together; his habits were generally immoral and drunken. He attempted to murder his wife by stabbing her with a knife. He had had several wounds on the head, was flighty, and always extremely violent. Attachment appeared, from the cast, to have been the principal organ in his cranial development.

Dr. Elliotson now commenced a highly interesting lecture by exhibiting a cast of the head of Cooper, who was executed at the Old Bailey. He had learned several particulars from the best authority relative to this man. It would appear that he was rather free on the point of appropriation, but had so much caution as to commit his robberies always *alone*. This was farther shown by his selling the watches he took, uniformly to the Jews. He had never committed murder before, nor even attempted it; and when he did so, it was in supposed self-defence. He was extremely passionate, as indeed was evident by his manner on the trial, particularly towards the judge; also by his conduct both to the surgeon and attendants. On one occasion he had attempted to hang himself, and at other times had taken arsenic and laudanum, for the purposes of self-destruction. The Doctor was present when he was taken from the condemned cell. He had evidently made up his mind that it would be useless to attempt further violence. On the trial it was endeavoured to prove him insane, but without success. He had shown no signs of insanity whatever, from the moment he was taken. He continually associated with abandoned women, and was very fond of his mother, but often spoke harshly to her when subjected to her admonitions. When his father died he fainted away. The phrenological developments argued great cunning. His head was by no means so large as Courvoisier's. The Doctor then stated the comparative dimensions of the two heads—Cooper's skull showed Attachment and Love of Offspring. Veneration was wanting. Benevolence was large; this was, in fact, the redeeming quality of his nature, but it was lost amidst antagonist organs. He had never been known to have committed violence, before the circumstances under which he did so, and which were such as almost invincibly to induce it. Dr. Elliotson next proceeded to show from this particular cast, that a specific form of the head in the parietal region indicated Want of Scrupulousness, Extreme Caution, and Violence of Disposition. As to his insanity, that was doubtful; persons with such heads need not alarm themselves. Their might be many such in the present company; they required education, and that should be *early, sound*, and *permanent*. All should have the best use made of their organization. When good organs were found, less moral culture was demanded, when bad, more. Human laws were necessary; all dread punishment under its various forms, whether fine, imprisonment, privations, or loss of rights, &c. He would further observe, that the law had no right to punish by inflicting pain. Society should be improved and protected, and crime thus prevented. Prevent crime by culture; unfortunately, both poor and rich are badly educated; there is too much false glare and attraction. Honours are paid to those who have not deserved them, to warriors and others who have done no good but much mischief to society. He condemned capital punishments as useless, cruel, and unwarrantable. They did no good, but infinite harm. It was quite a mistaken notion to suppose that they deterred men from crime. In the Netherlands there were no capital punishments. He had visited their prisons, and in them all classes of criminals were allowed to mingle together. He could not conceive how any human being was justified in shortening for one moment the duration of human life—of the term allotted to man for preparation for a future state. He had been assured by a clergyman, who had much conversance with condemned criminals, that their penitence was rarely genuine; besides, the possibility of the conviction of an innocent man should deter from so extreme a course. Look at the rabble who attend to witness an execution. The sight was most disgusting, not only in England, but in France, and every where else. The effect of such exhibitions was to harden the mind and diminish the horror we naturally feel of destroying human life. It was not fair, not right, thus to demoralize society: other punishments might be resorted to. Every mind has some spark of virtue—you may find humanity in a den of robbers, and modesty even in a brothel. All have one grand and solemn object of attachment.—Dr. Elliotson next alluded to the various modes of torture practised in different ages and countries. Death by burning, the rack, mutilation, dungeons, cages, &c.; and said, that cruelty, whether it extended to the destruction of life or not, was not necessary to punish or prevent crimes. All might be affected by proper training. It is now well ascertained, that the head may alter its form by moral cultivation. There are certain limits beyond which the capability of increase or diminution cannot be carried, but that capability exists. As is the body generally, so also is the brain particularly. We know not before-hand how far we can go, how much is to be done, or how little. There is, however, a certain extent of improvement possible. Dr. Elliotson next adverted to the circumstance of the habits of the parent influencing those of the offspring in the lower animals—in sheep, in the Highland cattle, in terriers, woodcocks, bees, &c. He showed how much could be done by training in these—man being at the head of the animal kingdom, it were singular if he too were not susceptible of improvement. He concluded with an expression of a fervent hope, that mankind would devote more attention to the organic improvement of their species; and announced the next meeting of the society, for males only, again that day fortnight, at the same hour. About one-third of the audience consisted of ladies, who evinced considerable interest in the observation of the lecturer.

FOREIGN LIBRARY OF MEDICINE, SURGERY, AND THE COLLATERAL SCIENCES.

[Exclusively compiled for the "MEDICAL TIMES," from French, Italian, and other Continental Periodicals.]

MAILLOT, F. C., et PULL, J. A. A., *Aide-Mémoire Médico-Légal, de l'Officier de santé de l'armée de terre*—The Military Surgeon's Medico-Legal Adviser, 8vo. 6s.——OLIVER, N. C. P. M. A., *Nouvelle Méthode de traiter et guérir la goutte*—New Method of treating and curing the Gout, 8vo. ——JAUBERT et SPACH, *Illustrationes Plantarum Orientalium*—or, a Collection of new and scarcely-known Plants in Western Asia.—[This work will form 5 vols. in royal 4to, each containing 100 plates, and about 30 sheets of text. Each livr. contains 10 plates. Price 15s. Livrs. 1 to 4 are published.]——*Encyclographie des Sciences Médicales*, Sep. 6s.——DEMAUGEON, J. B., *Physiologie Intellectuelle ou l'Esprit de l'Homme considéré dans ses causes physiques et morales*, 8vo. 8s.—Intellectual Physiology, or the Mind considered in its moral and physical causes.——BECQUEREL, M., *Traite de Physique consideree, dans ses rapports avec la Chimie et les Sciences Naturelles*—Natural Philosophy considered in regard to its connection with Chemistry and the Natural Sciences. *** The French works above announced, may be had through Dulau and Co., Soho Square.

PERISCOPE OF THE WEEK.

NERVES OF THE TONGUE.—Panizza's experiments on these nerves are confirmed by a case published in an Italian paper. A man 52 years old, after suffering for some time from wandering pains in his limbs, and being actively treated for them, was attacked by pain in the head and dulness of sensation in the left side of the face. The latter slowly extended over the right side also, and to the interior of the face, and ended in complete insensibility of every part supplied by the fifth nerves. Sight, hearing, and the sense of smell were unaffected. Many experiments were made to determine his power of taste; and it was found perfect for all sapid substances: he could distinguish the qualities of each article of food at his meals as well as he could when in health, and could discern the change and loss of savour which ensued when he kept them in his mouth. From the loss of common sensation, however, swallowing was difficult: he could not drink a large quantity at a time, and he was often choked in the attempt to swallow fluids. He was treated with electricity with slight temporary advantage. He died of intercurrent disease, but his body was not examined.

HYPOCHONDRIACAL OPHTHALMIA.—A middle aged man, subject to gout, rheumatism, and disorder of the abdominal organs complained of confusion of head. During the day and while in the act of walking he had frequent attacks of faintness, followed by general perspiration. He was sensible of a sudden spasmodic constriction of the right eye-ball, as if it were confined and pressed in the socket, accompanied by an actual twitching upward and downward of the upper eyelid. Objects appeared as if surrounded by a gauzy halo: the patient was unable to read, in consequence of the letters appearing to swim before him, writing was less difficult, although he was continually apt to carry the pen beyond the paper. The eye itself, beyond a slightly diminished activity of the lachrymal gland, betrayed nothing morbid. There were no objective symptoms; the patient's whole attention was engrossed by his disease, which he was disposed to consider by turns of a congestive, nervous, arthritico-metastatic, &c., origin: he sought eagerly the society and conversation of oculists; disconsolately anticipated the total loss of vision; the patient had, moreover, at a former period suffered from hypochondria, hence the belief that the affection was of an hypochondriacal or psychical origin.

INSECT ORIGIN OF SMALLPOX.—At the Institute, on the 4th of July, M. Serres mentioned the following fact, seeming to favor the hypothesis of animalcules in smallpox. By covering each pustule with a glass capsule, which is kept for some days in its place, he has seen the process of eruption either go on or languish, or be completely abortive, according as the glass was transparent or more or less opaque. This influence was evidently due to the contact of the air. The experiment, he adds, was not merely curious, for it led to a modification of some of the hygienic measures adopted in smallpox. Previously patients were generally placed in situations as well aired and lighted as possible; but now one knows that dark situations are far better for this kind of disease, and that this change alone is enough to ensure the most favourable progress of its evolution. The success at La Pitié was never more complete than during one year when all the patients with small-pox had, of necessity, to be put into a low, ill-aired, dark ward, a sort of cellar. The confluent cases there went on as favourably as was possible. At present, in the same hospital, they are moved from the first floor into the *rez-de chaussée*, and they do well there.—M. Serres took this occasion to mention that he had seen between 1700 and 1800 cases of smallpox in private and in hospital practice, and that he was certain that the number of those affected with smallpox after vaccination was not greater than that of those who had smallpox twice.—[A contemporary suggests that it may be the *light*, not the *good air*, which is favourable to insect development. May it not be both?]

THE PHYSIOLOGY OF THE SPLEEN.—The Spleen, is supposed by some, says, Dr. Benson, to prepare the blood for the liver, and by allowing it to stagnate there, to fit it better for the secretion of bile. Others think it is a sort of diverticulum for the blood going to the stomach; and that when the latter is full, and engaged in digestion, that then the blood is prevented from entering the spleen, and directed to the stomach. Tiedemann and Gmelin consider it an appendage to the lymphatic system —that it secretes a reddish fluid, which is carried to the thoracic duct, and increases the coagulating power of the chyle. Dr. Hargrave, concludes that its chief use is to receive the blood, as a temporary reservoir, or diverticulum, when any obstruction in the heart, lungs, or liver, renders it necessary that they should be relieved from the pressure of that fluid. The absence of valves in the splenic veins permits of regurgitation, and other circumstances render this opinion probable. He also conceives that it performs a similar office for the mucous membrane and the skin. When the blood is driven from these membranes by cold or rigors, it is received into the spleen for the time, and returned to the general circulation, as soon as the balance of the circulation is restored in these organs. Certainly the phenomena of intermittent fevers go far to support this opinion.—Sundry other uses have been assigned to the spleen. Soemmering gives an amusing catalogue of them. It was supposed to be—the seat of laughter; the cause of sleep; the seat of venereal excitement, from which the blood was directed to the genital organs; or that it gave origin to the semen in some way or other; that it formed the wax of the ears; that the serum which moistens the viscera exuded from its pores; that it formed the blood from the gastric fluid; that it absorbed and elaborated the nutritious juices from the intestines: that the nerves imbibed their nutritious juice from the spleen, and carried it to the blood to perfect that fluid; that it secreted some sort of acid, which was carried by the vasa brevia to the stomach, or by its own vein to the heart, to temper the alkaline nature of the chyle; that it concocted (coquere) some atrabiliary humour, which it transmitted to the liver by the vena portæ; that it was a sponge, to allow of the stagnation of the blood; that it secreted some fine humour to temper the bile: and that this was carried by the absorbents to their principal trunk, or by the veins to the liver, or by an excretory duct to the duodenum; that it was a sponge, possessing the power of sending the blood into the arteries or veins at pleasure (pro arbitrio;) that the globules of the blood were formed in it, being shaped in a kind of mould by the help of the absorbents; that it was merely to balance the liver by its bulk and weight; that it was of very little use; that it was of no use at all.—Soemmering's own opinion was that it prepared and fitted the blood for the secretion of bile. And Paley, in his beautiful remarks on the "Package" of the viscera, suggests that the spleen may be merely a *stuffing*, a soft cushion to fill up a hollow, which, unless occupied, would leave the package loose and unsteady. Perhaps, Soemmering, Paley, Tiedemann, and Hargrave are all, to a certain degree, right, and that the spleen, like the nose, the mouth, the urethra, and many other organs, serves more than one useful purpose in the economy. The fact that it has been removed in experiments on animals, and after accidents in men, without affecting the health, would prove that it has no function essential to life to perform, and renders it probable that it may be subservient to several less important, though doubtless, useful purposes. It does not appear that the spleen has any well-marked animal sensibility in its healthy state; neither does it show any contractility when stimuli are applied to it; but it possesses a power of expanding and contracting its texture, to receive and expel blood, in a very eminent degree, after the manner of erectile tissues.

PROPERTIES OF ARTERIES.—(*From a Correspondent.*)—The relation between the elastic and contractile properties of the arterial system, might have been argued from the influence which its different portions are known to exert on the circulation. In the large vessels, the object is not merely to adapt their capacity to the amount of blood contained, but also to render its successive progression continuous, and this may justly be considered as their most important function. It is obvious that a physical elasticity would suffice for such a purpose, and consequently this property should be the main feature of large arteries. We do not infer that elasticity, independently of a vital contractility, is calculated to resist the continued impulse of the circulation. Contractility thus comes to be a minor item in their character, and it is for this reason that so many physiologists have failed to detect it. Berzelius, Nysten, Bichat, Wedemeyer, and Muller, could not perceive the slightest contractions in the large arteries when excited either by powerful galvanic and electric stimuli, or by mechanical irritation; and yet, these vessels are possessed of a low degree of contractility, as already hinted, and as proved by the experiments of Hunter, Parry, and Williams. The reverse of this obtains in the small arteries, where the agency of contractility and not that of elasticity is required. That these vessels are endowed with considerable contractility is evinced in the experiments of Hales and Wedemeyer. From these remarks it may be deduced, that whilst elasticity is mainly characteristic of the large arteries, contractility is so of the small, and it is interesting to find that the respective structure of these vessels confirms such a conclusion. According to Heale, the inner portion of the external coat consists of pure *elastic tissue*, forming a layer of tolerable thickness in the large arteries, which *diminishes* in direct proportion to their size. And it has been long observed, that the middle or *contractile* coat *increases* relatively in size as the arteries decrease in calibre. This view of the subject is that taken by Hunter, and it is curious to remark, that his notion of the muscularity of arteries is abetted by the recent researches into their microscopic structure.

MEN WITH THREE TESTICLES.—Dr Macann, staff-surgeon now at Coventry, mentions the case of a recruit having with the two normal and fully developed testicles, a third occupying the right side of the scrotum, and in every way perfect as the other two. It was situated within the scrotum, between the groin and the proper testicle of this side, with which, however, it did not seem to be in immediate contact, but to be suspended, as it were, by a shorter cord, or hung up in a separate sac; in

fact, it seemed as if it had dropped from the abdomen after the other, but had not been permitted to fall so low in the scrotum as to touch it. In consequence of this arrangement the lower testicle was not at all pressed upon by the upper. On the left side the spermatic cord was perfectly natural in all respects, and was easily traced from the groin to the testicle to which it belonged. On the right side, however, the cord was much thicker than natural at its upper part, where, in fact, it consisted of two cords, one of which was distinctly traced into the upper testicle on this side, and the other, much longer into the lower testicle. In each of these parts, as well as in the cord on the left side, the vas deferens could be distinctly felt, like a piece of whipcord, between the fingers. Mr. Prankerd, of Langport, furnishes a second case perfectly similar, except in the fact, that the supernumerary body occupies the *left* side. Dr. Macann's case appears to have been congenital—Mr. Prankerd's however, has this singular explanation, as to cause:—Whilst a very young child, a nurse-maid had, in play, crushed the testicle with a pair of tongs and on recovery from the injury it was found that the testicle was divided, and has ever remained so since; gradually increasing in bulk with the growth of the person. In both men, there appears to have been great sexual vigour.

Quinine in Typhus.—At the instance of Signor Broqua, a medical practitioner at Piacenza, the sulphate of quinine has been used in frequent doses on patients suffering under typhus fever, in the Hopital Cochin, in Paris. The doses, administered by Broqua himself, were usually from one and a half to three grains hourly, during both day and night. In the French hospital they varied, in different cases, and at different periods of the disease, from fifteen to ninety grains in the twenty-four hours. M. Laurent presents in the "Archives Generales de la Medicine," for Sept. 1842, a summary notice of its effects, as observed in eleven cases treated at the Hopital Cochin; from which it appears that the most marked influence of the remedy was on the pulse, the frequency of which it uniformly diminished. Many unpleasant symptoms resulted d ur.ng its employment, such as a dry ness and heightened color of the tongue and fauces, which probably prevailed throughout a great part of the alimentary canal, being accompanied with intense and sometimes insatiable thirst; pain in the chest and epigastrium; abundant diarrhea, and occasionally bloody stools; frequent vomitings, which ceased on abandoning the use of the remedy; deafness and ringing in the ears, which did not invarably cease with the cessation of its employment, &c. Certainly, out of the above eleven cases in which the sulphate of quinine was tried at the Hopital Cochin, only one terminated unfavourably; but M. Lourent is, notwithstanding, by no means sanguine of having found in it a remedy for typhus superior to others; and, indeed, were it so, its expense would be urged as an insuperable bar to its general adoption.

Curious Researches in Phthisis.—Rayer asserts that he has ascertained the following facts respecting this disease. It is of ell chronic diseases that which is most common to man and animals. In man, and the other mammifera, the tuberculous matter is readily distinguished from recent pus; in birds its characteristics are less marked; and in lower animals still less so. Pus, however, in the mammifera, and especially in the horse, after a long persistence in certain organs, undergoes successive changes, in the course of which it sometimes assumes the aspect of tuberculous matter. The internal softening of tubercles is not attributable to inflammation; but their external softening is, on the contrary, most commonly by the inflammation of the adjacent tissues; and almost always the tubercular matter is mixed, in the latter case, with globules of pus. The calcareous concretions seen in the lungs of man and animals must not always be considered as tuberculous. They are often, in man and in the horse, the residue of purulent deposit. Phthisis is in our climate and in France, by far the most frequent chronic disease in animals the natives of distant countries. It attacks not only animals from warm, but others from cold climates, as the rein-deer, &c. It is comparatively rare, however, in the solidungula and caroaria; and the horse and dog are much more subject to cancer than phthisis. The bony disease presented by the monkey tribes, particularly those of South America, when suffering from phthisis, appears to be analogous to the deformities, swellings, and spongy softening of the bones in phthisical and scrofulous children. Similar diseased alterations are observed in the bones of carnivorous animals transported hither. Phthisis though hereditary, is seldom congenital, even in a rudimentary form. The seminal fluid of phthisical persons is remarkably destitute of animalculæ.

Preparation of the Lactate of Iron.—According to Pagenstecher, the lactate of lime, which is easily obtained from sour milk, and lactate of ammonia, may be employed to advantage in preparing the salt of iron. Common carbonate of ammonia of commerce is added to the solution of lactate of lime, the carbonate of lime removed by filtration, the liquid concentrated by evaporation at a gentle heat to the consistency of a syrup. This concentrated solution of the lactate of ammonia is mixed with six times its weight of alcohol of sp. gr. 0·879, and a concentrated aqueous so lution of protochloride of iron now added, the quantity of which is best determined from the lactate of lime used for the ammonia salt; for 100 parts of the lime salt, CaO, L + 36 aq, 38 parts protochloride of iron containing 16·48 iron. Soon after mixing the liquids the solution becomes turpid from the separation of the lactate of iron, which continues forming, and is completed within 24 to 36 hours. The mixture then presents the appearance of a white syrupy mass, resulting from the separated crystals of lactate of iron; it is freed from the liquid portion by straining and pressure, edulcorated with alcohol, strained and pressed again, and then dried, spread out in thin layers between folds of bibulous paper at a gentle heat. The preparation thus formed is a light crystalline powder of a whitish yellow colour and agreeable ferrous taste. To obtain it perfectly white it should be dried in vacuo over sulphuric acid. It may also be formed direct from the lactate of lime without first converting this into the ammonia salt; but the less solubility of that salt in alcohol, and the difficulty of freeing the preparation from adhering chloride of lime, renders the employment of the lactate of ammonia preferable. A slight residue of perchloride of iron, arising from an oxidation of the prootosalt, is moreover of no con equence in preparing according to the above method, as the lactate of the peroxide of iron is insoluble in alcohol.

THE MEDICAL TIMES

A Journal of English and Foreign Medicine and Medical Affairs

No. 167. Vol. VII. LONDON, SATURDAY, DECEMBER 3, 1842. PRICE FOURPENCE. Stamped Edition, 5d.

For the convenience of Subscribers in remote places, the Weekly Numbers are re-issued in Monthly Parts, stitched in a Wrapper, and forwarded with the Magazines.—Orders for the Stamped Edition [10s. 10d. per Half-year, Post free in advance,] are received by any Bookseller or Newsman, or may be directed to F. A. Cartwright, Esq., at the Medical Times Office, (late Lancet Office), London.

ON THE LAWS OF THE DEVELOPMENT OF ORGANS; OR, TRANSCENDENTAL ANATOMY APPLIED TO PHYSIOLOGY.

By E. R. A. SERRES, Member of the Institute, of the Academy of Medicine, Professor to the Museum of Natural History, Paris, &c., &c., &c.

Summary.—Relationship between Organogeny and Comparative Anatomy—Parasitical life of beings—Division of the organisms so much more marked as we descend in the scale of life—Various states of the organs in the course of their formation, repeated in a permanent manner by their analogues in the series of animals—Heart—Os Hyoides—Sternum — Superior Maxilla—Kidney.—Prostate. — Uterus.—Penis—Clitoris, &c.

In my previous observations, I have shown you the relationship which human embryogeny bears to comparative anatomy. In the organisms of the animal kingdom, we see produced upon a large scale, and in a permanent form, the various conditions traversed in so rapid a manner by the organisms of the human embryo. In the embryo, this passage is rapid, in consequence of the energy of its vital powers; while in the lower animals, organic life is comparatively feeble, and unable to traverse the course marked out for the human species. I will now enter more fully into this subject.

In the human species, we name the early part of the period which the product of conception passes in the uterus embryonic. This period is devoted to the formation and development of the organisms essential to extra-uterine life. These organisms formed, the product then takes the name of fœtus, which usually happens about the seventh month. Every living body is termed an embryo, which is developed by generation upon a body larger and of the same species as itself, to which it primarily adheres, but from which it becomes detached to pass from a communicated to a separate and peculiar state of existence. Thus, in its rigorous acceptation, embryogeny embraces only the duration of the parasitical life of a living body, during which those organisms essential to a free and independent existence are developed. The study of the formation of these organisms, that of the connecting media between the embryo and the parent, of the especial coverings which surround it, and of the temporary organs required during this borrowed life, constitute then the domain of this branch of science. Every one, however, must be aware, that life is not uniform throughout the animal kingdom. Very limited in some beings in whom the parasitical state never entirely ceases, it becomes, on the contrary, exceedingly complicated in others, especially in man, where it attains the highest degree of development. The parasitical life of the embryo undergoes the same variations: some being detached earlier than others from their parent, it necessarily results that in their subsequent life they retain the sum of organic developments which they had acquired at the moment of their separation.

Parasitical life being then devoted to the formation and development of organisms, it follows, as a general rule:—1st. That the number and perfection of the organisms of an animal will be in direct relation with the time employed in their formation, and consequently directly proportioned to the duration of their embryonic life:—2nd. That the more the organisms are limited and imperfect, the shorter will be the free and independent existence succeeding to the embryonic life of the animal;—3rd. That the shorter the independent life, the more rapid and numerous the reproduction of the animal;—Lastly, in some species, or even in entire classes of animals, life may be, and is, sometimes, carried on with organisms arrested at some period of development, proper only to embryonic life. The more we descend in the scale of life, the more imperfect we shall find the organisms: for nature strictly proportions her means according to the ends she has in view.

As a general law, we find that as we descend from man among the vertebrata and invertebrata, the organisms become proportionally disassociated or simplified; so that on arriving at the bottom of the animal scale, we find them reduced to their most simple outline or elementary form. Another law not less general is the following: if we trace the development of a complicated organism in the superior vertebrata or in man, we find that it commences by a state of remarkable simplicity, but that each of the transformations which it undergoes complicates it more and more, until it arrives at the normal state which ultimately characterizes it. This is not all; for if we compare the organology of the inferior animals with the first stages of the organogeny of the superior vertebrata, we find that the primary outline of the organisms corresponds in both cases. So that, the organisms of the human embryo in the course of their development traverse successively the states presented by the same organisms in the families, genera and classes composing the animal kingdom. Considered in this point of view, the animal series is but a repetition of the embryonic transformations; the one is the reproduction of the other. We now, however, come to more particular facts.

Let us take the heart as a first example: very complicated in man, the mammifera and birds, this organ becomes gradually more simple in reptiles, fishes, the crustacea, the mollusca, the annelida and insects. In each of these steps it loses, either a portion of its elements, or a part of its muscular structure, becoming in insects and the annelida a simple straight or curved canal. So also with the young embryo, the heart commences under the form of a canal, at first almost straight, then curved, thus in form and structure corresponding exactly with the heart of insects, the annelida, and some crustacea. At the second stage of formation, the auricles become added to this canal, producing three distinct cavities; a ventricle in the middle, and two auricles placed upon the sides and at a distance, exactly in the same manner, as in the heart of the acephalous mollusca; then the two auricles are brought into contact; in the embryo of the bird these two sacs are united into one; so that we have a larger ventricle, and a single auricle still more developed. A condition exactly similar is found in the cephaloid mollusca. These two stages of formation of the heart in the vertebrata represent then in a transient manner the permanent condition of this organ in invertebrated animals. But, as we know, this viscus is not arrested at this state in the superior animals; in the course of its developments, the single pouch of the auricles becomes divided into two cavities by the interposition of a central partition; and this partition, according as it is more or less complete, represents that of certain fish, and some reptiles, as the tortoise, &c. Lastly the ventricle in its turn becomes divided into two by the same mechanism as the auricles; and that stage where the ventricular partition is not perfectly closed in birds and the mammifera, is an exact repetition of the permanent arrangement of the ventricles in the snake tribe, especially the adder. We may remark, that in the embryogeny of the superior vertebrata, as well as in the anatomical scale of fishes, reptiles, and the invertebrata, the development of the auricles generally precedes that of the ventricles. Thus are the various stages of formation of the fœtal heart an exact repetition of its permanent conditions in comparative anatomy. The same may be said of the blood-vessels. For at the periods when the heart represents a mere canal, all the blood-vessels of the embryo are venous, the same as in the annelida and most acephalous mollusca. The arteries do not acquire the structure which distinguishes them from the veins, in the embryo of vertebrated animals, till the muscular coat of the left ventricle is perfectly formed. The same is observed in the cephaloid mollusca and crustacea.

We see, then, that when an organism is found in a divided state in the human embryo, we may be certain of meeting with it in a similar condition in some animals arrived at the term of their development. The multitude of pieces of bone in the cranium of fishes, compared with the number of points of ossification in the fœtal cranium, is one of the most striking examples of this general law of organogeny. We find a similar confirmation of it in the separate pieces of which the sternum is composed in certain mammifera, in reptiles and fishes. These permanently isolated portions are represented by the primitive nuclei, so perfectly distinct, of which the human sternum is composed from the second to the fifth month of intra-uterine life. The same may be said of the os hyoides.

In the adult man, the superior maxilla is a single bone forming, as we know, the greater part of the face, and incasing the organ of smell and part of that of taste. These senses being limited in the human species, the bone which protects them is also limited; it is simple and undivided. But in proportion as we descend from man, these senses increasing in capacity and extent, the protecting bone is extended with them: but while expanding it is divided; its constituent materials are isolated. The first isolation, or fractional state, found in the human embryo, is that of the incisor bone of the herbivora and ruminantia. This osseous element is so distinct in animals, it stands out so prominently from the rest of the bone, that unable to refuse considering it as a distinct piece, according to the views of Camper, who considered its absence the characteristic of man, anatomists directed their attention towards discovering it in the human embryo; in this they soon succeeded, for the traces of its division sometimes remain even beyond birth. This fact, placed beyond all doubt, by Goethe and Vicq-d-Azyr, serves to explain the formation of one portion of the alveola. But, independently of the other cavities contained in its substance, this bone presents a hole for the passages of the sub-orbitar nerve and artery. These cavities requiring for their formation a large number of pieces of bone, I endeavoured to discover them in the young embryo; now, from the third to the fourth month of conception, I constantly found in the human embryo five distinct pieces subsequently uniting to form the superior maxilla. M. Geoffroy Saint-Hilaire also, in examining the head of the crocodile, ascertained in these reptiles the permanent division of these five pieces. The crocodile then represents permanently the condition offered by the embryo at the third month in reference to this bone. We have before said, that in the human embryo, the kidney, which in the adult forms a single organ, is in its original state a mul-

tiple or many-lobed viscus. I have sometimes seen it formed of eight, more frequently of six, or of four small kidneys on each side. Every anatomist must have seen this arrangement, which is the primitive or normal state of the organ. Now, in descending from man to the animal kingdom, we shall find this transient condition of the embryo presented in a permanent manner by the various species of adult mammifera; thus in the elephant the kidney consists of four lobes, in the ox of twelve or fourteen, in the otter of two, and generally speaking of two also in the feline tribe, as well as in most birds. The organogeny of the human embryo is then but a transient comparative anatomy, presenting to us in a successive manner the permanent conditions of the lower orders of animals. It was for a long time a debated point whether the *thyroid gland*, was a single or a compound body. Without the intervention of organogeny, this dispute might have been interminable. For, as Haller first observed, this gland, simple in the adult, is constantly double in the young embryo, the right being perfectly separated from the left, and their union not being accomplished till an advanced period of embryonic life, in a similar way to what sometimes takes place with the sublingual glands, the amygdalæ at the root of the tongue, and the two kidneys in front of the aorta. The prostate again, although of a distinctly lobular appearance, presents, in the adult, a body of a uniform and connected aspect; in the embryo, on the contrary, it is composed of four distinct and isolated lobes. Towards the fourth or fifth month, the two inner lobes become united, and the prostate then seems to be composed of three lobes only. Later still, that is to say, between the sixth and eighth months, these three lobes become intimately united one with another, forming, like the kidney, a single organ, but in which we may, by careful dissection, discover the traces of its primitive organization.—The same may be said of the uterus, which in the carnivora and herbivora, presents manifest traces of division, and which in some species of animals, as the *cavia* of Gmelin, and especially the hare, is composed of two distinct organs, opening separately into the vagina. So in the human embryo between the second and third month, this viscus is formed of two distinct cavities; thus passing through the organization of the lower animals before reaching its ultimate state of unity in the adult female. We here see a striking resemblance between the uterus, the prostate and the thyroid; a powerful argument in favour of the analogy of these three parts.

We know that the primitive homogenety of the two sexes is one of the most curious discoveries of embryogeny. Originally there is neither male nor female; at a second stage, all are apparently females (I say apparently); then the organs, seemingly female, transform themselves into male organs. All females, at a certain period of their formation, have then the appearance of being hermaphrodites, and at a certain period also we might without careful examination mistake males for females. These latter appearances manifest themselves in the human embryo toward the end of the second or the beginning of the third month, and in the ox, the sheep, the dog, and the cat, at the first third of their formation. This disguise in the sexes arises from the constancy in the mechanism of their formation. At first projecting forwards, the genital organs are not enclosed in the pelvis. The clitoris and the penis form a very marked projection below the rudimentary abdomen. The clitoris and vagina, at first divided along their entire length, become united in front, and present an enlargement at their summit, which is also divided upon its inner surface. Below this body, we find the skin bifid presenting two small folds; the internal, proceeding towards the root of the enlargement which terminates the body from whence the clitoris or penis arise; the external, enclosing the latter organs within its folds. The first of these folds ultimately constitutes the nymphæ in the female and the prepuce in the male; the external gives birth to the labia majora and the scrotum. On separating the first fold, we see a small opening, which is the external orifice of the urethra, equally distinct, at this period, from the extremity of the clitoris and from the glans. In a female embryo of four weeks I could discover no vaginal opening. When the pelvis is united in front, it forms a very projecting angle, from the branches or rami of which arise the crura, which by their junction constitute the clitoris and penis. The more acute this angle, the more the genital organs project outwards, and it is at this period especially, that is to say from the fortieth to the fiftieth day of embryonic life, that these little beings would all be taken for males, if we considered only the external appearance of the genital organs; as, in like manner, at the commencement of the second month they might all be mistaken for females, when the cutaneous folds, from which the scrotum and labia majora are to arise, have not become entirely united in the male. Now, this embryonic similitude is found in an exact state of repetition in many adult animals. The volume of the clitoris, says M. Geoffroy Saint Hilaire, equals that of the penis in several species, even among apes, and the resemblance is so great, that females are often taken for males. In some species the glans penis, as well as the clitoris, is bifurcated. The rabbit is remarkable in this respect; in it the penis is an exact repetition of that of the embryo between the fourth and fifth week, in the same way that the cornua of its uterus are a striking copy of that of the human embryo from the fortieth to the fiftieth day.

In the commencement, the uterus of the young embryo represents two small tubes drawn near together, but not united one to another. In the second stage, the two vaginal extremities of these tubes are joined, though not intimately. In the third, they are incorporated and intermingled. The neck of the uterus, previously double, becomes unique; but at the same time that this union takes place in front, a separation of the remainder of each tube is accomplished posteriorly; and which produces the uterine cornua. At the fourth stage, the incorporation which has taken place between the two necks is prolonged behind, and the formation of the body of the organ begins. This body, unique in front, is still double behind, from the persistence of the remains of the two tubes entering into the formation of the uterus. Lastly, at the fifth stage, these tubular remains, becoming united like the rest of the body, give rise by their association to a simple uterine body. Let us now apply these principles of human organogeny to the comparative anatomy of this organ. The uterus, properly so called, exists only in the mammifera; its form and character are, however, very variable in the different classes of animals. I have shown that the varieties in form of the fœtal uterus are dependent on the original separation of this organ into two parts, and on the various stages through which it passes before reaching its ultimate state of unity. We will now see whether we cannot trace a resemblance in the animal kingdom; whether we shall not find in the uterine forms of the mammiferæ, the various stages of formation traversed by this organ in the human embryo. The first stage of uterogeny is represented by the *monotremata*, in which the uterus, properly speaking, is absent. Their oviducts terminate in two dilatations, completely separated one from the other, and opening in a species of *cloaca*. The *echidnus* and *ornithorhinchus* are, in this respect, intermediate between birds and the mammifera. The second stage is shown in the *marsupialia*. The dilatations of the inferior extremity of the tubes in this class of animals, instead of remaining separate, as in the *monotremata*, are brought into immediate contact, in the same manner as in the frog; they are not, however, united into a single organ: the uterine body, as well as the vagina, is divided by a central partition into two separate cavities, producing, as it were, two sets of genital organs. The same may be observed in the kangaroo, and, occasionally, according to Tiedemann, in human monstrosities. The third stage of uterogeny is characterized by unity of the vagina and plurality of the uterine opening by distinct orifices. This is the case with most of the rosores—the hare, the rabbit, the beaver, the rat, the mouse, the guinea pig. This condition has been met with by Morand, Dupuytren, and Tiedemann, in the human race. These stages, as I have said, may all be traced in the early formation of the human embryo. Let us, however, follow the conversion of these two uteri into a single organ, bearing in mind that, in the human race, this takes place from before backwards, or from the neck towards the fundus of the organ. Now, a course of development exactly similar is found in the mammifera. In the carnivora, some rosores, the cetacea, &c., the unity of the uterus has already commenced; but the neck, properly so called, is not fully developed; the uterine cornua are still distinct posteriorly, being sometimes straight, as in the dog and the cat, sometimes bent or curved back, as in the mole and the hedge-hog. In the ruminantia, the neck is much more developed posteriorly, and a small but perfect cavity is formed, communicating with the two cornua which are strongly curved backwards. These two processes show, in some measure, a tendency to union in certain cases of gestation; for when there are two ova, one in each cavity, a part of their membranes is carried along the neck, from one cornu to the other.

Up to this point the body of the uterus is double in the strict acceptation of the word. But in the *solipedes* we have a partial unity in the body. Here we have a single uterine cavity constituting about two-thirds of the uterus; but the posterior third is still double. These remnants of the uterine cornua have, however, lost the active share which they previously enjoyed in the act of gestation. They no longer receive the ovum; gestation is entirely carried on in the uterine cavity. In some of the monkey tribe again, the form of the uterus is still more approached to that of the human species; but its axis is more longitudinal, and its fundus less rounded and concentrated than in woman.

PRIVATE COURSE OF OPERATIVE SURGERY.

By J. NOTTINGHAM, Esq., Member of the Royal College of Surgeons of London.

LECTURE V.

Before, during, and after the performance of surgical operations, means are employed for limiting as much as possible the quantity of blood lost by the patient. Before operations, as well as during the time of their performance, we avail ourselves of pressure on the arterial trunks to prevent a dangerous effusion of the vital fluid immediately after the knife has been employed; the larger arteries which have been divided are secured by ligatures, before the edges of the wound are approximated; we afterwards trust to position, temperature, and quiet, &c.; each of which may be made to tell favourably on the circulation, and to share the work of preventing hæmorrhage. In the modern practice of surgery, the arresting of hæmorrhage by the actual or potential cautery, or by styptic drugs, is seldom had recourse to; and when we see a surgeon arm himself with such weapons, we are apt to think that he suspects the efficiency of his better resources, or that he is not *au niveau* with the present state of chirurgical art. Before the period when the circulation of the blood began to be generally understood, surgeons must have experienced great difficulties in the arresting or preventing of hæmorrhage; and the history of the surgical department of the healing art contains records of many appalling practices employed to stop dangerous bleeding, such as plunging the stump after amputation into boiling pitch, searing its sensitive surface with the hot iron, or applying strong acids or other corrosive substances to it.

The progress of anatomical and physiological knowledge, the invention of the tourniquet, and the study of the true scientific means of restraining hæmorrhage have long since driven all such horrid practices out of sight, and their record only tends to show how many and how varied the degrees of progress in any art must be, before it arrive at a state approaching that to which the term perfection can be applied.

In amputations of the extremities, with the exception of the smaller operations about the hands and feet, the main artery of the limb is compressed against the nearest bony surface, by the fingers of an assistant, sometimes aided by a pad of some material, which may be easily thrust down upon

the arterial trunk, or with the aid of a tourniquet to encircle the limb, or of some other apparatus more or less analogous in its effects, such as the compressor of Dupuytren, or the Italian tourniquet, or jointed bow of steel, which some of the English instrument makers have supplied us with of late. There is, doubtless, some disadvantage about every apparatus here alluded to, and if the assistant of the surgeon could be relied upon, and his strength were not likely to fail him, there is little doubt but his fingers would, upon the whole, be better than any tourniquet or compressor; for they occupy less space, and are not so much in the way of the operator, and do not interfere with the retraction of the divided parts, complaints which are brought against the tourniquet; nevertheless, it is not so easy to get the end of the fingers nicely laid over the course of the artery in some cases, as might at first be supposed, and every one who has acted as assistant on any occasion, and has compressed the femoral artery with his fingers during an amputation of the lower extremity, knows how fatiguing this effort soon becomes, and has wished, I would venture to say, that the tourniquet were there instead of his fingers, whether the surgeon would like it or no. On all occasions, the tourniquet should be present, whether employed or no may depend upon circumstances, and, by the tourniquet, is to be understood, the instrument commonly known by that name, for which various substitutes may be found if occasion require. In any case of alarming haemorrhage where the tourniquet is not at hand, the turn-stick which may easily be made, supplies its place very well; a pad, piece of leather for the tape to pass through, the tape and stick being all that is required; and these might readily be made out of some article or other to be found in every man's abode.

For very obvious reasons, the application of the tourniquet is confined to the extremities; compression of arteries by it within the trunk being impossible, as also of those in the neck, because of the parts with which they are associated, and of their wanting bony support sufficient for this purpose. We need not here do more than allude to the attempts at compressing the aorta through the abdominal parieties, as in cases of uterine haemorrhage, &c.; as these matters do not belong to the subject with which we are occupied.

Arterial branches outside the skull occasionally require to be compressed to arrest haemorrhage, or with the hope of curing aneurismal tumours, their vicinity to the bone facilitating this mode of treatment; this, however, will be afterwards alluded to. We may now proceed to notice the different applications of the tourniquet, and of pressure applied by other means in cases of amputation of the extremities. The great arterial trunk of the lower extremity may be compressed; 1st. against the body of the pubes—by the fingers of an assistant, with or without the aid of some pad or instrument, such as the bow of a key covered with lint to assist the effort we have to make. 2ndly, against the upper and inner part of the thigh bone; and, 3rdly, against the lower and back part of the thigh bone, or in the popliteal space with the aid of the tourniquet; either of the two latter modes will suffice in amputation of the leg, the first or the second must be chosen in amputation of the thigh.

Before the application of the tourniquet, many surgeons pass a of piece linen around the limb,—to prevent the tightened-strap doing any injury to the corresponding portion of integument,—the plan, however, adopted by Professor Ferguson, seems to be at once the neatest and most convenient,—using a small calico roller for a pad, and turning the free end of it once or twice round the limb, and then leaving the roller over the situation of the vessel, to be afterwards pressed home upon it by the tightened belt of the tourniquet. Before the tourniquet is applied, the girth should be sufficiently drawn out, and the buckle along with it, lest in tightening the instrument the buckle come in the way. It would seem scarcely necessary to offer any particular directions regarding the mode of applying the tourniquet, its application will be found easy to every one who has studied its mechanism; but a little care should be taken that the instrument is in perfectly good order before it be applied, and that the strap be sufficiently strong to resist the utmost turning of the screw without danger of breaking. In applying the tourniquet to the upper part of the thigh, the instrument may be outside the limb, the roller or pad of course inside, or over the artery, the buckle in front of the limb, or between the other two, and the same arrangement of the parts of the tourniquet may obtain in applying it to the upper part of the humeral artery; in its application in the popliteal space, which is well suited to cases of amputation of the leg, especially where it is desirable that very little blood shall be lost; the tourniquet may be in front, above the patella, the roller (here required to be thicker) behind, the buckle outside the limb. After the instrument is applied it is to be tightened gradually, until pulsation can no longer be felt on the arterial branches below; after which any additional pressure is unnecessary. If the tourniquet be applied as far as possible from the seat of the operation, it is less in the way of the manœuvres of the surgeon, or of the retraction of the integument, so that as a general rule, it is better to take advantage of these conditions, than to seek the saving of a very small quantity of blood by applying it very near to the parts to be divided.

After the removal of a portion of a limb by amputation, the divided arterial trunks cannot always be readily detected, and it may be requisite that the assistant should lessen his pressure, or gently slacken the tourniquet, so as to afford the surgeon an opportunity of seeing clearly the divided vessels whence the arterial jets come forth; a very slight turn of the screw will often suffice, and greater slackening of the hold should be avoided until the divided vessels are secured by ligature, when the tourniquet should be immediately made quite loose, although its strap may be left encircling the limb, the instrument itself lying near, ready to be employed in case of accident, such as secondary haemorrhage, &c. In the axilla, the axillary artery may be easily and effectually compressed against the head of the humerus, either with the ends of the four fingers alone, or aided by a suitable pad; and here it may be well to recollect that the artery is situated at the union of the anterior with the middle third of the axillary space; in the groin, as before-mentioned, the commencement of the femoral artery may be compressed against the body of the pubes, the fingers, or the fingers and pad being employed, as in the other case, and if we notice carefully the form and position of that part of the bone immediately above the thyroid foramen, we shall at once perceive that the right direction of the pressure to be exerted here is downwards, backwards and inwards. In amputation at the hip or shoulder joint, the femoral and axillary artery are compressed by an assistant, who introducing his fingers into the wound, seizes these vessels before their division by the knife of the surgeon.

Having briefly noticed the mode of compressing the arterial trunks of the upper and lower extremities, chiefly in connection with amputation, we proceed to state the method of compressing other arteries, such as may now and then be required in various cases of disease or injury. On account of the vicinity of the larynx and trachea, we seldom attempt to compress the primitive carotid; this, however, may be done, particularly at its upper part, by pressing the vessel against the corresponding portion of the cervical spine.

The facial artery, or external maxillary, at the anterior border of the masseter muscle, may be compressed, perhaps, more easily than any other in the body, one finger sufficing to press the vessel against the corresponding portion of the lower jaw; and the temporal may be compressed in the same way, in front of the external ear. We need not offer any remarks on the compression of other small arteries of the same region; for if a wound on the head be attended by troublesome bleeding, compression of the wound itself, on account of the smallness of the arteries and their anastomoses, is better than an ineffectual attempt to find the chief arterial source of the haemorrhage. With the aid of a common door-key, the bow or handle wrapped with lint, I have compressed the subclavian artery on the first rib, during amputation of the arm, near to the axilla; this, however, is a doubtful sort of proceeding, the motions of the clavicle and shoulder disturbing, with every writhing effort of the patient, the repose of the part where the pressure is exerted. The axillary artery may be compressed by the fingers, as before remarked against the head of the humerus—and it has also been proposed, by Dahl, to compress it below the clavicle on the second or third rib; in this situation, however, it is so thickly covered by muscle, that such compression can scarcely be effected by the fingers, and Dahl contrived a peculiar tourniquet for the purpose, which, however, has never been employed. The brachial artery may be compressed against the humerus, recollecting its course on the inner border of the biceps muscle, corresponding, as it were, to the course of the seam in the coat-sleeve. Where the pulse is generally felt, the radial artery may readily be compressed against the bone,—the ulnar in the same manner, in the lower third of the fore-arm, between the tendons of the flexor sublimis and flexor carpi ulnaris; but this compression, like that of the radial artery, is seldom employed. The digital arteries are readily compressed at the line of union of the inner and anterior aspects of the fingers. I have known life to be lost by wounds of the iliac arteries, and also by wound of the internal mammary; so that, to be able to command, more or less, the arterial system of the trunk of the body, is an acquisition to be desired by the surgeon. It is not long ago that a man, in Liverpool, lost his life by being stabbed in the groin, the iliac artery being wounded. In such cases, death has often taken place before the surgeon could possibly arrive by the side of the sufferer; if in time, compression of the aorta may be attempted in the neighbourhood of the umbilicus, first bending the body forward, and relaxing the abdominal muscles—the ends of the fingers being employed alone, or they may be aided by a suitable compressor; in this way the aorta may be compressed against the lumbar vertebrae; and it may be added, in cases of uterine haemorrhage, this plan appears on some occasions to have been attended with considerable success; but in haemorrhage occurring after labour, the womb itself may be compressed through the abdominal parieties, and the bleeding appears occasionally to be in this way arrested. In a case which came under my observation some few years ago, serious haemorrhage took place from the internal mammary artery into the cavity of the pleura. The sufferer, a young man, had been struck on the chest by a fellow-workmen with a chisel; the cartilage of the third rib was divided by the blow, the artery behind it cut across, and the cavity of the pleura opened. Such cases rarely occur; but should we meet with a similar one, and have reason to think that dangerous haemorrhage was going on, it appears to me possible to stop it; but how this could best be done is the question: supposing, then, that the application of cold produced no effect, could we introduce a pair of strong, curved, and good biting forceps through the wound, and so lacerate the divided ends of artery, and finishing each portion with a little torsion, in this way stop the bleeding? or could we not employ an instrument, shaped like a double key, or with wards on both sides; to use a homely comparison, resembling the little instrument with which cooks raise the kitchen grate; for supposing the wound to be large, as it was in the case alluded to, such an instrument even covered with a little lint, might be introduced into the pleural cavity, by way of the wound, turned, and then withdrawn, until the divided vessel underwent the requisite compression? The ligature *en masse* might be applied above and below the wound, dividing the integument in the direction of the artery, perforating with a sharp probe the pleura (previously injured by the wound), inside the artery, and through the aperture carrying the aneurism needle armed with its thread, which should next be made to bulge out the intercostal muscle outside the artery, where the point of the probe might open a way for it outwards, and the artery and parts connected could thus be tied and compressed *en masse*; this mode of proceeding being resorted to because of the want of that space between the ribs, which would be sufficient to allow us to find the artery, and to isolate it in the ordinary way. The dorsal artery of the penis may be easily

compressed by seizing the root of the penis between the fore finger and thumb. When pressure cannot be applied at a lower point, the external iliac may be compressed against the brim of the pelvis through the abdominal parietes, the force being applied obliquely outwards. The femoral artery is easily and often compressed, as before alluded to, against the pubes, the pressure to be exerted obliquely so as to close the calibre of the vessel upon the ileo-pectineal eminence; this may be done with the fingers with or without the aid of a pressing instrument, with the compressor of Dupuytren, or even with the tourniquet. The vessel may also be easily compressed against the femur at the upper part of the middle third of the thigh, the direction of the force should here be backward and outwards; the popliteal artery may be compressed behind the knee joint, with or without the tourniquet; the latter, however, had better be used on account of the great quantity of adipose tissue in the neighbourhood of the vessel; instead of compressing the arteries below the knee-joint, it is usual to command their circulation by compression of the femoral.

So much for the means of preventing hæmorrhage applied before the operation,—we now proceed to offer some remarks on the means of saving blood during the operation.

During the removal of large tumours for example, arteries of considerable size are sometimes divided, sending forth a stream of blood, which, if continued beyond a very short time, might endanger the life of the patient. Such a case I met with about ten days ago; where, in removing a tumour weighing some pounds, from the back of the shoulder and side of the neck, large arteries entering the centre of it were cut across; with the aid, however, of prompt and adroit assistant, the hæmorrhage from them was readily stopt; an assistant placing the end of his finger upon a divided and bleeding vessel, which he commands for a moment with the left hand, until it is seized with the forceps held in the right, and has a ligature applied to it. In some operations where blood oozes in considerable quantity from the cut surface, as, for instance, on the removal of tumours, &c., but where there is no hæmorrhage, *per saltum*, which is visible from distinct arterial branches, pressure exerted around the wound will sometimes suffice to arrest the bleeding. In such operations as those at the hip and shoulder joints, the axillary or femoral artery may be seized by an assistant during the operation before the knife of the surgeon arrives at it, who may compress the artery and raise the flap in which it is situated out of the way of the surgeon at the same time. In the operation for hare-lip, on children of delicate constitution, the instrument for holding and at the same time compressing each section of the lip, made by Mr. Weiss, will prevent any loss of blood worthy of mention; if this instrument be not employed, each portion of the lip may be so held between the finger and thumb, as nearly to answer the same purpose.

Tying arteries previous to operation, to prevent hæmorrhage during its performance, is a practice seldom had recourse to, although it is barely possible that such a thing might be desirable. If life were menaced by pressure on the larynx, &c., from enlargement and disease of the thyroid body; but few surgeons would now-a-days attempt the removal of the offending mass. Such an attempt has, however, appeared warrantable to skilful and prudent surgeons, Roux and others. "On one occasion," says Professor Fergusson, "in a case where the affection (of the thyroid) produced more than usual annoyance, I witnessed an attempt to remove a portion of this gland, but the operator was speedily obliged to desist, in consequence of the profuse hæmorrhage; a needle was thrust across the swelling (which was chiefly in the middle or isthmus), and a stout double thread was tied tightly round the most prominent part, by which the blood was restrained; a slough followed, and the patient was relieved of a troublesome, tickling cough, which had resisted all other means of cure. Roux, after expending more than an hour in removing a portion of this gland about the size of an orange, and applying forty-seven ligatures, lost his patient fifty-six hours afterwards. It appears to me somewhat doubtful, whether we could not remove a portion of the thyroid body without the great danger that is generally apprehended—by combining the previous ligature of some of its sources of arterial supply with ligature *en masse* practised upon it at the time of the operation; to these considerations, however, we will afterwards revert. During an operation, the ligature of an artery already exposed before its section with the knife, is occasionally necessary,—such a precaution I have known to be required with regard to the profunda femoris, in removing a tumour from the thigh. Hæmorrhage from veins is seldom alarming during the performance of operations; it may be caused by the pressure of the tourniquet, or it may be caused by the only partial pressure of the arterial system of the limb where the tourniquet is not employed, or it may be caused by a want of free circulation through the lungs, arising from violent efforts sometimes made by the patient during operations; where the cause is on the spot, as in either of the former instances, its removal is easy; where it is pulmonary, as in the latter, the patient should be directed to draw in his breath three or four times very freely, for this enlivens the pulmonary circulation, and occasionally puts a stop at once to that which appeared an unmanageable and formidable bleeding. During some operations the employment of the little self-closing forceps, significantly called Mr. Liston's 'bull-dogs,' to hold the arteries until they can be tied, will be found an useful adjunct to other means; these appear to be more especially applicable during removal of the breast, or in operations of a similar nature.

ON THE MINUTE STRUCTURE OF THE BRAIN, IN THE CHIMPANZEE AND IN THE HUMAN IDIOT,

Compared with that of the perfect Brain of Man; with some Reflections on the Cerebral Functions. By JAMES MACARTNEY, M.D.

MANY years ago I discovered, with only a common pocket lens, a reticulation of fine white fibres, immediately under the surface of the cerebrum, in birds. This first led me to believe that the medullary fibres, as they are called, extended farther, and were more subdivided than had been hitherto supposed. I have since been able to demonstrate to medical students, and to several teachers of anatomy, the existence of those filaments in every part of the brain, by simply moistening the substance of the organ, during the dissection, with a solution of alum in water, which has the effect of slightly coagulating, and rendering the final filaments visible, which, in their natural condition, are transparent. By this means, I have shown that the filaments (which I prefer to call sentient, instead of *white* or *medullary*) everywhere assumed a plexiform arrangement, and that the most delicate and intricate plexuses were to be found inclosed in the grey or coloured substance of the brain. This fact proves the analogy between the coloured substances of the brain, and the ganglia of the nervous system, in which there is a close reticulation of nervous fibres. I have long been in the habit of considering the magnitude and form of the entire brain, and of its several parts as being merely subservient to the number, extent, and connexions of the various plexuses, in which, and especially in those occupying the coloured substances, I believe the sensorial powers of the brain to reside.

A chimpanzee (the pigmy of Tyson) having some months ago died in Dublin, and the dissection of it having been intrusted to Mr. Wilde, I proposed to him that I should undertake the examination of the animal's brain, in my own manner. Tyson and others had described the bulk, shape, and external appearance of the different parts of this creature's brain, but the intimate structure had never been examined by any anatomist.

I shall now lay before the academy an account of what I observed in the brain of the chimpanzee, and likewise in those of two idiots; by which it will appear that the brain in the latter possesses a still lower degree of organization than in the former animal.

Dissection of the Brain in the Chimpanzee (*Simia Troglodytes.—Lin.*)—The *external form* bore so great a resemblance to the human brain, that, excepting the difference in size, the one might be mistaken for the other. The *convolutions* were as decidedly marked, and the proportions of the cerebellum to the cerebrum were exactly as in man. On the under surface of the brain I observed that the two white pea-shaped bodies, called *corpora candicantia*, were very indistinct; and they did not appear to be, as in man, the continuation of the anterior crura of the *fornix*. The *pons*, which unites the lateral lobes of the cerebellum, was, perhaps, rather flatter than in the human subject, and the fifth pair of nerves entered it, and passed for a little way distinctly, which is so remarkable in the sheep. The *pyramids* did not decussate to any extent; only two superficial bundles of fibres crossed. The *corpora olivaria* did not project distinctly, and the band which surrounds them was not observed. The structure internally of these bodies consisted of white filaments included in grey substance. The branches of the *arbor vitæ* were, perhaps, not so deep, but quite as numerous as in us. The white filaments composing the trunk were not so fine, nor so strictly interwoven, as in man, and, therefore, they were more easily distinguished. The *corpus fimbriatum* was of a long shape, and appeared to be composed chiefly of grey substance, and wanted the dentienlated edge. The part called *locus niger*, in the crura of the cerebrum, was a small, greenish-grey mass, of an irregular figure, and less than a pea, instead of the crescentic form, as in man: and it did not mingle with the white fibres of the crus. The *pineal* gland was large. It was removed in making a cast of the ventricles, and lost; it was not, therefore, ascertained whether it had any calcareous matter in it or not. The parts in the lateral ventricles corresponded very nearly with the same in man. The soft *commissure* was particularly strong, and held distinct white filaments. The *linea semilunaris* was faintly marked. The two anterior of the *tubercula quadrigemina*, called *nates*, were the smaller. The *fourth ventricle* was much prolonged into the lateral lobes of the cerebellum. The *grey substance* on the floor of the ventricle was not raised into the appearance of two ganglia, and there were no *white striæ*. The sentient or white filaments formed looser or less complicated plexuses, wherever they were examined, than in man, and I could not discover any of the delicate *arborescent filaments* in the base of the *corpora striata*.

Dissection of a Female Idiot, with Extraordinary Brain.—The whole mass of the brain was small, but the front part did not recede. The *convolutions* were rather small, but sufficiently deep for the size of the brain. The *lobes* of the *cerebellum* were not the one-third of the usual size. The *gyri* were scarcely distinguishable, and the divisions were few and shallow. The *arbor vitæ* had but two principal branches, and the subdivisions of these were few. The anterior part of the lobes was supplied by two clusters of membranous glands, filled with red jelly or albuminous fluid, such as we find substituted for the cephalous fœtuses. The *corpus fimbriatum* was indistinct, wanted the dentienlated margin, and the proper structure inferiorly, and was not half the proper size. The *pons* was exceedingly small, and its internal structure obscure. The *pyramids* were parallel cylindrical forms, and did not appear to decussate. The *corpora olivaria* had little prominence, and the coloured substance was deficient. The *locus niger* was imperfectly formed, and not of a dark colour. The *corpora striata* were very small, as also the white filaments contained in them. The *pineal gland* was rather of a large size, and contained a cluster of round soft bodies, in place of the calcareous granules. In fine, the character of the whole brain was imperfection of intimate structure. The plexuses were not intricate, and the grey substances pale, and not in sufficient quantity. This person had been a patient in the Whitworth Hospital. The account I received of the state of her intellect from the house pupil was, that she was foolish, and that he could never get a rational answer from her. She was extremely ugly, with projecting jaws and teeth, and an idiotic countenance. She was an

unmarried woman, but not a virgin, notwithstanding the great deficiency in her organ of amativeness.

Dissection of the Brain of a Male Idiot.—The *cerebrum* was small, and the anterior lobes especially so. The *cerebellum* projected beyond the posterior lobes of the hemispheres. The *convolutions* of the cerebrum were small, particularly those of the anterior lobes on the *left side*,—they were so imperfectly developed, and so closely connected to each other, that they had more the appearance of a tuberculated than of a convoluted surface. The *olfactory nerves* were small, and very deficient in grey substance; indeed, all the coloured parts of the brain were rather pale. The *pyramids* could scarcely be distinguished, being extremely small, and confounded in the projection of the corpora olivaria; they did not appear to decussate; the one on the left side was particularly small. The left hemisphere of the brain was smaller than the one on the right side. The *tubercula quadrigemina* were of an equal size, and a grey colour on their surface. The *pineal gland* was large, semi-transparent, and contained very little of the gritty matter. On the surface of the *left* crus of the cerebrum there was a green tinge observed, which, on being cut into, proved to be the *locus niger* in a disorganised and nearly dissolved state. There were no *white striæ* in the fourth ventricle. The *plexus* of white filaments at the roots of the *olfactory nerves* was very plain on the *right* side, but very imperfect on the *left*. The *brain* was tolerably firm. The *spinal marrow* was hard and the *cerebellum* was soft. The structure, as well as form of the parts in this brain, was imperfect throughout, but most remarkably so on the left side; the want of agreement between the two sides would necessarily impair the functions of the brain.—The first deviations from the perfect brain of man appear to be with respect to the following parts:—The locus niger, the corpus fimbriatum, the white striæ in the floor of the fourth ventricle, the decussation of the pyramids, the distinction of the anterior crura of the fornix, the corpora olivaria, the degree of intermixture of the sentient or white filaments in the arbor vitæ, the corpora candicantia, and the existence of calcareous granules in the pineal gland.—It is remarkable that many of these parts are not found in the first stages of fœtal life, and some of them not until after birth. The pineal gland, according to Meckel, is not perfect until the seventh year of infancy. The same parts also first decline, and ultimately disappear in animals, according to their scale of organisation; and further, it is chiefly with respect to these parts, that varieties of structure are observed in the brains of different rational human beings. I have found many deviations from the ordinary structure in subjects, without being able to ascertain what peculiarities of character belonged to them when alive; but, in one instance, of a deaf and dumb person, the white striæ of the fourth ventricle (with which the auditory nerves communicate) were imperfectly formed, were not subdivided, and did not unite with each other. If, therefore, we can ever arrive at correct notions of the functions of the brain, it must be by careful dissections of the interior parts of the cerebral organ, and by ascertaining the correspondence between the minute structure, and the endowments and dispositions of the different individuals; taking into account, at the same time, the influence of the various organs of the body, instead of ascribing to certain parts on the surface of the brain distinct and often opposing faculties, as Gall and Spurzheim have done.—It seems to be particularly absurd to suppose that the cerebellum, a part evidently as highly organised, and of as much importance as the cerebrum itself, should be designed to produce merely the sexual instinct. In animals that have the lateral lobes of the cerebellum very small, or who want them altogether, this instinct is stronger than in man. In those instances which are known of the absence of a part, or one lobe, or the whole cerebellum, no want of the venereal appetite existed; and a case is related of a person in whom the sexual desire was so ungovernable, that mechanic restraint became necessary; and it was found, after death, that both lobes of the cerebellum were wanting in this person. In animals that propagate only at particular seasons of the year, the testicles and ovaries are singularly developed at those periods, and afterwards decline, while at the same time no change takes place in the cerebellum. The abolition of the sexual instinct, by the extirpation of the testes, or of the ovaries, puts it beyond all doubt that this impulse does not originate in any part of the brain.—It would appear that all instincts depend upon the condition and state of feeling in those organs with the functions of which they are immediately connected; thus, the maternal instinct (at least in mammiferous animals) is in a great measure the result of the tension of the mammary glands. As soon as this is removed, by the absorbents carrying off the milk, quadrupeds lose all care and anxiety about their young. The cerebral organ would, perhaps, of all others, be the most unfit for the generation of instincts. The brain is destined to direct or control instinctive feelings, and, therefore, it cannot create them. If a person attempt to command any instinctive impulse to be felt, he will find it as impossible to do so as to rise from his chair, merely by willing it, without the aid of the muscles.—I have ascertained and demonstrated, by repeated dissections, that all the plexuses of the brain are continuous with each other; that no part of the nervous system is isolated; and consequently the different parts must exercise a mutual influence on each other. I have proved that the spinal nerves, as well as those of the brain, are not inserted in the same way as the roots of plants penetrate the earth, which has been heretofore believed, but that they are united with the parts from which they are supposed to arise, and that the spinal nerves, form a chain of communication with each other, after they enter the spinal marrow. It is in consequence of the integrity of the whole nervous system, that the various sympathies, both natural and morbid, exist between the different organs of the body. If the continuity of the sentient or nervous filaments were to be intercepted at any one place, their functions would be arrested at that point, in the same manner as the division of the nerve destroys sensation and voluntary motion in the parts to which the nerve is sent. —Some anatomists, it is true, have supposed that the various reticulations of the nerves, and the intermixture of the brain, were merely to bring them into contact, and that there was no incorporation of the sentient substances. This opinion is consequent upon another, as ill supported by facts —namely, that there is a subtile or nervous fluid, which carries impressions made on the nerves to the brain, and thus causes sensation; and that the same fluid, proceeding from the brain to the muscles, produces voluntary motions. It has never been, however, attempted to explain how this imaginary fluid could become the instrument of sensation or volition, more than the sentient substance itself. For my part, I am satisfied with the knowledge of the undoubted fact, that the peculiar matter which exists in the nerves and the white filaments of the brain, is endowed with the *power of feeling*—a power perfectly distinct from every other in nature; and I think it is equally obvious that the various modifications of sensorial function we observe are the result, and require for their production the multitude of subdivisions and reunions that take place in the sentient filaments of the brain and nerves. Voluntary motion appears to me to be the natural consequence of the connection between the central part of the nervous system, and the muscles which move in obedience to the will or desire of the individual.—*Transactions of the Royal Irish Academy.*

Spinal Irritation.—This disease, is supposed by Dr. Stilling, of Cassel, to be dependent on congestion in the capillaries of the spinal chord. He remarks, also, that wherever there is sanguineous congestion there is an exudation of serum through the parietes of the blood-vessels, which softens the surrounding structures; so that in *post mortem* examinations of persons who have died with the above disease the spinal cord has been found in all stages of ramollissement.

ACCOUNT* OF A CASE OF
SUCCESSFUL AMPUTATION OF THE THIGH
DURING THE
MESMERIC STATE,
Without the Knowledge of the Patient
Read to the Royal Medical and Chirurgical Society of London, on Tuesday, the 22d of Nov., 1842.

By W. TOPHAM, Esq., and W. SQUIRE WARD, Esq., M.R.C.S., Formerly House Surgeon to St. Bartholomew's Hospital

To the Royal Medical and Chirurgical Society.—Mr. President and Gentlemen:—*In detailing the circumstances attending the important case I have the honor of communicating to this learned Society, I shall abstain entirely from any preliminary remarks upon the supposed cause of the effects I have produced. I shall, still, call the state "Mesmerism," because the term involves no principle; it regards the phenomena only, and not the specific cause for them.—Whatever the agent may be, through which the Mesmeriser influences his patient, whether by a medium—some, or the entire portion of which, is already familiar to us, under another designation—or by a medium totally new to our experience, it becomes me not now to inquire.—The generality of men, when they hear of some novel phenomena, instead of testing* the truth *by experiment alone, endeavour to ascertain* the cause, *by their own powers of reasoning; and belief or disbelief, is made to follow the result. The startling phenomena of Mesmerism have but too frequently illustrated this remark.* To facts, *I shall, therefore, confine myself; and to such only as I can personally vouch for.*

James Wombell, aged 42, a labouring man, of a calm and quiet temperament, had suffered for a period of about five years, from a painful affection of the left knee. On the 21st day of June last, he was admitted into the District Hospital at Wellow near Ollerton, Notts.; no longer able to work, and suffering much pain. It was soon found that amputation of the leg, above the knee-joint, was inevitable; and, it was eventually proposed, that it should be performed, if possible, during mesmeric sleep.

I saw Wombell, for the first time, on the 9th of September. He was sitting upright, upon a bed in the hospital; the only position which he could bear. He complained of great pain, from his knee, and of much excitability and loss of strength from his constant restlessness and deprivation of sleep; for he had not, during the three previous weeks, slept more than two hours in seventy.

In the first attempt to mesmerise him, which occupied me thirty-five minutes, the only effect produced was a closing of the eyelids, with that quivering appearance, peculiar to mesmeric sleep; and, though awake and speaking, he could not raise them, until after the lapse of a minute and a half.

My attempt, the next day, was more successful, and in twenty minutes he was asleep. I continued to mesmerise him every day, except the 18th, until the 24th of September: his susceptibility gradually increasing, so that, on the 23rd, the sleep was produced in four minutes and a half. The duration of this sleep varied, continuing, generally, for half an hour; sometimes, for an hour; and, occasionally, for an hour and a half. But, with two exceptions (attempts to converse with him), I invariably found him awakened, though without being startled, by the violent pain from his knee; which suddenly recurred at uncertain intervals.

The third time I saw him, he was suffering great agony, and distressed even to tears. I commenced by making passes, longitudinally, over the diseased knee: in five minutes, he felt comparatively easy; and, on proceeding further to mesmerise him, he was sleeping like an infant. Not only his arms were then violently pinched, but, also the diseased leg itself; without his exhibiting any sensation: yet this limb was so sensitive to pain, in his natural state, he could not bear even the lightest covering to rest upon it. That night, he slept seven hours without interruption.

After constantly mesmerising him for ten or twelve days, a great change was observed in his

* From the pamphlet published by Baillière.

appearance. The hue of health returned. He became cheerful; felt much stronger, was easier, both in mind and body; slept well, and recovered his appetite.

On the 22nd of September he was apprized of the necessity of an early amputation. The communication seemed almost unexpected, and affected him considerably. I, this day, tried the experiment of mesmerising him against his will; proceeding by contact with the hands, charging him, particularly, to exert his mind to prevent my affecting him. During the process, he occasionally glanced at those near him; moving his eyes as he felt inclined, and, in twelve minutes and a half, passed into mesmeric sleep. The two or three previous days, it had been effected in six minutes. He informed me, subsequently, he had repeatedly called to mind the intelligence just received, and the torture which he must endure; but he soon found the influence irresistible, and presently lost all consciousness. The anticipated loss of his limb, however, that night, destroyed his natural sleep. Next day, though found still fretting, restless, and in consequent pain, he was yet, by my touch, asleep in four minutes and a half.

I was then absent, and did not see Wombell until the 28th. He was looking healthy and cheerful; his natural sleep was sound and regular; and his pain soothed and diminished. I was now convinced that the operation might be safely attempted during mesmeric sleep, and, with the man's firm consent, it was fixed for the Saturday following.

On the morning of Saturday, the 1st of October, I again mesmerised Wombell, having done so the two previous days. This was done in the presence of Mr. William Squire Ward, of Wellow (the operator), and two other surgeons; in order that the previous mesmerism might tend, as I believed it would, to render his sleep deeper, when again mesmerised for the operation: and also to satisfy them of the state in which he would be, when that time arrived.

He slept an hour; and was roused by an attempt to converse with him. I then shewed them my power of affecting any one of his limbs, even when he was quite awake. At my request, he extended his arms alternately. By making two or three passes over each, without any contact, I so transfixed them, that, from the shoulders to the tips of the fingers, they became as rigid and unyielding as bars of iron, not to be unbent except by mechanical force, powerful enough to injure the limbs, and yet instantly relaxing throughout, and dropping to his side, from the effect of my breath alone. His right leg was affected in the same degree; and relief from immediate pain was frequently afforded, by making similar passes over the diseased one. Though the sensibility to pain was diminished, in the limbs thus affected, whilst awake, it was only during mesmeric sleep I found it totally gone.

At half-past one o'clock, we proceeded to Wombell's room, to make the necessary arrangements. From the suffering inflicted by the slightest movement, it was found impossible, without needless torture, to place him upon a table. The low bed, on which he then lay, was therefore raised upon a temporary platform. Ten minutes after being mesmerised, he was drawn, by means of the bedclothes beneath him, towards the end of the bed. The movement, however, excited that pain which had so often aroused him before, and now it did so again. There was something quite excruciating in the suffering which the state of the knee produced: for, I had seen him, whilst in mesmeric sleep, pricked to some little depth, in other parts of the diseased limb, without being disturbed or conscious of it. To preclude the necessity of any further movement, his leg was now placed in the most convenient position which he could bear. Shortly afterwards, he declared that the pain had ceased; and I again mesmerised him, in four minutes. In a quarter of an hour, I informed Mr. Ward that he might commence the operation. I then brought two fingers of each hand gently in contact with Wombell's closed eyelids; and there kept them, still further to deepen the sleep. Mr. Ward, after one earnest look at the man, slowly plunged his knife into the centre of the outer side of the thigh, directly to the bone; and then made a clear incision, round the bone, to the opposite point, on the inside of the thigh. The stillness, at this moment was something awful; the calm respiration of the sleeping man alone was heard: for all other seemed suspended. In making the second incision, the position of the leg was found more inconvenient than it had appeared to be; and the operator could not proceed with his former facility. Soon after the second incision, a moaning was heard from the patient, which continued, at intervals, until the conclusion. It gave me the idea of a troubled dream; for his sleep continued as profound as ever. The placid look of his countenance never changed for an instant; his whole frame rested, uncontrolled, in perfect stillness and repose; not a muscle or nerve was seen to twitch. To the end of the operation, including the sawing of the bone, securing the arteries, and applying the bandages,—occupying a period of upwards of twenty minutes,—he lay like a statue. Soon after the limb was removed, his pulse becoming low, from the loss of blood, some brandy and water was poured into his throat; which he swallowed unconsciously. As the last bandage was applied, I pointed out to one of the surgeons and another gentleman present, that peculiar quivering of the closed eyelids, already alluded to. Finally, when all was completed, and Wombell was about to be removed, his pulse being still found very low, some sal volatile and water was administered to him; it proved too strong and pungent, and he gradually and calmly awoke.

At first, he uttered no exclamation; and, for some moments, seemed lost and bewildered; but after looking round, he exclaimed, "I bless the Lord to find it's all over!" He was then removed to another room; and, following immediately, I asked him in the presence of those assembled, to describe all he felt or knew, after he was mesmerised. His reply was, "*I never knew anything more; and never felt any pain at all; I once felt as if I heard a kind of crunching.*" I asked him if this were painful? He replied, "*No pain at all: I never had any; and knew nothing, till I was awakened by that strong stuff*" (the sal volatile). The "crunching," no doubt, was the sawing his own thigh bone. He was left easy and comfortable; and still found so, at nine o'clock that night: about which hour, I again mesmerised him (in a minute and three quarters), and he slept an hour and a half. I may further add, that on the Monday following, the first dressing of his wound was in mesmeric sleep. Of this dressing, usually accompanied by much soreness and smarting, he felt nothing; slept long after it was completed; was ignorant of Mr. Ward's intention; and, after awakening, remained unconscious of its having been done.

Mr. W. S. Ward's own valuable statement, in accordance with his personal observation and care, prior and subsequent to the operation, he has kindly permitted to be appended to my own: and thus, to render complete the narrative of this case: which I leave, without a syllable of comment.

W. Topham.

Middle Temple,
Oct. 28, 1842.

SECOND STATEMENT.

Mr. President and Gentlemen:—

Being a party concerned in offering the present paper, for reading before your learned Society, I feel that, as a member of your own profession, and the operator alluded to in the preceding pages, some observations are due from me, in addition to those already brought before you by my friend, Mr. Topham.

The circumstances under which the operation was performed are of so novel a nature, that they may afford much ground for discussion, if the members of the profession, to whom I have the honour of addressing these observations, will calmly deliberate upon them; and, without prejudice, examine the subject, which (should further experience confirm the anticipations that may reasonably be entertained, from the happy results of the present trial) holds out such a boon to the surgeon, whose province it is, and whose study it has for ages been, to mitigate the poignant sufferings that "flesh is heir to."

The case, to which the attention of the Society has been already called, was one of very extensive ulceration of the cartilages of the knee-joint, of four and a half years standing, the consequence of neglected inflammation of the synovial membrane, produced by injury, which was treated by a quack, in the first instance, but did not come under my own notice until about three years before his admission into the District Hospital, at Wellow; when, supposing ulceration to have commenced in the cartilages, I ordered absolute rest and the usual treatment, which was only adhered to for ten days; when, in spite of every remonstrance on my part, he returned to his ordinary employment (an agricultural labourer) in his still crippled state.

He then fell into the hands of other practitioners, whose discipline was less rigid, and whose prognosis was more sanguine than mine. I frequently met him, and occasionally warned him of the eventual loss of his limb, if he persisted in using it. His last fair prospect was a promised cure by cupping; but this having produced no relief, he applied for admission into the hospital. At this time the disease had far advanced; the slightest motion of the joint was attended by the most excruciating agony; his nights were almost wholly sleepless, in consequence of the painful startings of the limbs; his pulse weak and rapid; his face constantly marked with a hectic flush; his tongue foul, and appetite gone. He was now confined to his bed, but could not bear a horizontal position. The joint was supported by a light splint; poultices, fomentations, &c., were applied; attention paid to his general health; opiates, quinine, wine, &c., prescribed to get him into a fit state for the operation (which I deemed inevitable), *without any apparent benefit*: but, on hearing that Mr. Topham was coming into the neighbourhood, I determined to request him to try the effects of Mesmerism upon him; with a view, not only of tranquillising the system, prior to the operation, but, if possible, to procure such a degree of insensibility to pain, as to render the man unconscious of the operation itself; having long desired to see this accomplished as the *summum bonum* of Mesmerism.

I was, however, obliged to leave home, from indisposition, at this period; but daily received reports of the progress made upon my patient: and, on my return, on the 27th of September, —about three weeks after the commencement of the Mesmerism,— I was as much astonished as I was delighted, to observe the improved condition of the man. He had, now, much more the hue of health; his nights were more quiet and tranquil; his appetite had returned; and, in fact, such was his state, that had I not known the previous history of the case, much doubt must have arisen, in my mind, as to the propriety of, immediately, amputating the limb. It is true, there was, still, the pain, on the slightest movement of the joint; and, still, some of the same painful startings at night; but he no longer appeared to be suffering in his general health, which, on the contrary, was greatly improved. nevertheless, I felt assured, notwithstanding all this in his favour, that there was too much disease to admit of a final recovery.

As I had quite determined upon not attempting to remove the limb, while the patient was under mesmeric influence, unless I was convinced of its safety, and had opportunities of seeing him in that state; and, moreover, not without the man's own full concurrence; on the 29th, I requested Mr. Topham to mesmerise him; when I was delighted to find his susceptibility so great. When asleep (if I may use the term), his breathing was unaltered, his pulse tranquil, and about 80; his waking was slow and gradual, and without the least start; and, I found, he was insensible to the prick of a pin.

Under such circumstances, I saw no grounds for fear or hesitation; and having obtained the patient's consent, or, rather, at his own urgent request, I fixed the following Saturday, 1st of Oct., for the performance of the operation.

The patient (as has been already stated) was lifted, with his bed, upon a platform, and, although he was considerably excited, by hearing the cries of another patient, upon whom I had been performing a tedious and painful operation in an ad-

joining room, he was soon put into mesmeric sleep. but, as I wished him to be placed in the usual position, with the limbs extended over the end of the bed, an attempt was made to draw him down with the bed-clothes; but this occasioned so much pain, as to awake him. I was, now, somwhat embarrassed; as his position on the bed, with his extremity lying in close contact with it, was so very unfavorable to the operator; but having proceeded thus far, I was unwilling to mar the first attempt at lessening the horror and pain of a capital operation; although I must confess, I was by no means sanguine of success. The patient was again put to sleep; previously to which, a surgeon present raised the limb about two inches from the mattress, by resting the heel upon his shoulder and supporting the joint with his hand; promising also, if the man should awake, instantly to draw him down, so as to allow the leg to extend beyond the edge of the bed.

In a few minutes, Mr. Topham said he was quite ready; when, having adjusted the tourniquet (the very unfavorable position of the patient precluding the possibility of otherwise compressing the artery), I proceeded to perform the operation, as has been described. Having made the anterior flap, without the slightest expression of consciousness on the part of the patient, I was under the necessity of completing the posterior one, in three stages. First, by dividing a portion of the flap on the inside; then a similar portion on the outside. This proceeding (which of course was far more tedious and painful than the ordinary one) was rendered necessary, to enable me to pass the knife through, under the bone, and thus complete the whole; as I could not sufficiently depress the handle to do so, without the two lateral cuts.

Beyond what has been already so well described by Mr. Topham, I need only add, that the extreme quivering or rapid action of the divided muscular fibres *was less than usual;* nor was there so much contraction of the muscles themselves: I must also notice, that, two or three times I *touched the divided end of the sciatic nerve, without any increase of the low moaning,* described by Mr. Topham; and which, to all present, gave the impression of a disturbed dream.

The patient is doing remarkably well; and sat up on Sunday last, to eat his dinner,—just three weeks from the operation; and he has not had a single bad symptom; none, even of the nervous excitement, so frequently observed in patients who have undergone painful operations, and who have suffered much previous anxiety, in making up their minds.

On dissection of the joint, the appearances fully verified my diagnosis. The cartilages of the tibia, femur, and patella, had been entirely absorbed, except a much-thinned layer, partly covering the patella. There was deep, carious ulceration of the exposed ends of the bones; and especially on the inner condyle of the femur; which had wholly lost its rounded shape. Some coagulated lymph was effused upon the surface of the synovial membrane, in several places; and the joint contained a certain quantity of dark-colored pus.

It is not my intention to trespass further upon the valuable time of the Society, by presuming to stand forward as the champion of Mesmerism generally: a task to which I feel myself to be totally incompetent. For a long time, I had been a sceptic; and, long, a "cui bono" querist: when, through the kindness of Dr. Elliotson, a few months ago, I was allowed an opportunity of examining for myself, the power of that agent in producing coma; in rendering rigid the muscles; and in causing, to a certain extent, insensibility to pain. I saw, and was convinced, that my opposition was ill-founded; and the result of this conviction has been the present successful and flattering trial; which is a sufficient answer to those who are incredulous, only, as to any benefit to be derived from it: for there can be very few, now, even of the most bigoted objectors, who will venture to deny its powers in producing coma. This, too, in the calmest temperament; not merely according to the frequent supposition, in the highly nervous young female, but, even to *utter insensibility* in an agricultural labourer, aged 42; to which class, I need scarcely add, nervous excitement, in the common acceptation of the term, is almost an entire stranger.

Be it observed, also, so complete was the susceptibility, that coma was quickly produced, under the most unfavorable circumstances; as, when in extreme pain from his disease; when using his own volition, to the utmost, to counteract it; and when on the table, with the fear of the operation before his eyes.

Although the single experiment, we have detailed to the Society, is scarcely sufficient to set the question completely at rest; is it *not* of a sufficiently encouraging nature, to demand an immediate repetition, by those of my professional brethren, to whom the splendid institutions of the metropolis offer such frequent opportunities?

W. Squire Ward.

CASES OF PERITONEAL SECTION
FOR THE
EXTIRPATION OF DISEASED OVARIA BY THE LARGE INCISION FROM STERNUM TO PUBES, SUCCESSFULLY TREATED, WITH OTHER CASES OF EXTIRPATION OF ANOMALOUS TUMOURS, &c. &c.

By CHARLES CLAY, Member of the Royal College of Physicians, London of the College of Surgeons, Edinburgh, and Lecturer on Medical Jurisprudence &c. Piccadilly, Manchester.

(Concluded from page 112.)

CASE THE FIFTH

The remarkable features presented by this case at first, and more so when the tapping had been effected, rendered the prospect of recovery all but hopeless. The extent and number of adhesions were such, that it appeared impossible they should be overcome, without effecting irreparable injury; and yet this case recovered more rapidly than any of the previous, and contrary to the expectations of every one present at the operation.

MRS. HARDY.

I have reported the following case that it might not be said I only made public the fortunate cases. It is analogous, as far as the peritoneal section is concerned, but entirely different as to the why such an operation was attempted. Of the cases previously related, those of *ovarian disease were decidedly and remarkably successful, neither age, extent of adhesions, size of tumour, length of disease, nor quantity of ascitic deposit offered any obstacles to their recovery.* The case of Mrs. Dillon, I am inclined to think, (and regret I had not an opportunity of confirming it by a post mortem examination,) was not an ovarian disease, but a tumour of another and widely different character, one that would very soon have destroyed the patient. Had not indulgences been resorted to of a character incompatible with recovery: there is no doubt on my mind that she would have lived much longer after the operation, still it was sufficient to prove how little danger arose from the incision of the peritoneum, that being almost entirely healed before death.

The last case was truly an unfortunate one still, it in no degree detracts from the operation *for encysted ovarian tumours.* The seat of the disease and the disease itself offered less prospect of success, whilst the latterly rapid growth and frequent severe accompanying pains of the tumour shewed that its malignant character would soon have been developed to the full, and terminated fatally, all these were fully confirmed by the post mortem examination. Mrs Hardy æt. 45, never had any children, appeared about the size of a female in the eighth month of utero-gestation. The tumour had a lobulated character, of a hard unyielding feel, not the slightest deposition of fluid could be detected either in the abdominal cavity or within the walls of the tumour; it appeared not to have the slightest peritoneal

Simple diet continued, with the addition of a little weak mutton broth once a day.	Motions	Urine	Sleep	Pain	General Surface	Tongue	Pulse	Temperature	From the Termination of the Third Day after Operation to the end of the Case.

attachments and could easily be moved under the integuments, lastly it occupied more of the right than the left side. Having been made fully alive to the danger of extirpation, still she was urgently desirous of having it removed and in the hope that its attachments would not be serious. The operation was commenced on the morning of the 17th, in the presence of Dr. Radford, Mr. Walker, Mr. W. C. Vandrey, Mr. G. Southam, surgeons, and Mr. Winterbottom. The incision to the extent of thirteen inches was quickly made, and as had been anticipated no peritoneal adhesions existed; the tumour however presented very different appearances to encysted ovarian tumours, it was of a bright pink colour, hard as a piece of boiled liver, and composed of numerous small lobes with acute edges similar to the lobes of the liver, the mass appeared upwards of 12lb. in weight. I soon discovered to my mortification that its attachment was of a very broad character at its base and highly vascular, no less than the full length of both fallopian tubes and the greater part of the uterus itself formed a part of the tumour. I had now gone too far to recede, no alternative presented but extirpation of the whole mass; at this period of the operation my patient began to faint, (and it should here be stated that for some time past she had been subject to syncope of an alarming character,) ligatures were placed round the fallopian connections as well as the central uterine attachment, still considerable hæmorrhage occurred when the parts were separated. The mass included in the ligature was too great to have any decided effect on the vessels supplying the diseased mass, which were very numerous, and from the repeated attacks of syncope following each other rapidly during our endeavours to secure them, it was evident the shock of the operation would be too great; the vessels were secured, the integuments brought together and the patient placed in bed, after which every means were put in force to rally her but in vain, attacks of syncope continually occurred and she finally sank about an hour and a half after the removal of the tumour. Some time after, a *post mortem* examination was instituted, when it was found that the part severed was so charged with vessels, that the section presented mouths of vessels almost as numerous as the cavities of a piece of sponge and some of them very large; there was but a small portion of the neck of the uterus and the os uteri that was not amalgamated with the substance of the tumour. The tumour weighed 13lbs. was entirely solid and highly vascular, and its character evidently such as to promise an early and speedy termination of life, even had it remained, if any injury or excitement had occurred. No one could have regretted the unfortunate termination of this case more than myself; my medical friends felt it equally and though it cannot be quoted as an argument against the operation *for ovarian tumours*, yet it offered an excellent caution against attempting the removal of tumours of a more solid formation, which I presume are always connected with viscera of more serious importance than the ovaria. It may also be observed that persons prone to syncope and that of an alarming character, are perhaps not fitted to undergo an operation of such magnitude: in such, the mere shock of the operation must often be attended with a fatal issue.

Before I conclude these papers, I may mention two other cases of ovarian disease, that furnish a hint or two worthy of consideration.

MRS. ORMROD.

Mrs. Ormrod, Chadwick Street, Manchester, consulted me in September last (1842.) She was 62 years of age, enormously distended in the abdomen by fluid. I proposed paracentesis abdominis, and performed it in two places without being able to bring away more than two or three pounds of a thick glairy fluid, of a brownish tinge. I diagnosed this to be a case of encysted ovarian disease, and as my patient was too old to promise a favourable result by operation, and even supposing such a means had been proposed, she was of too timid a character to undertake it, I therefore advised the steady perseverance of the following formulæ:—

℞. Tinct. Opii ʒiss.
Subcarbon: Potassæ ʒij.
Infusi. Gentianæ ℥viij. M.
℥i. ter in die
℞. Linim: Saponis ℥ii.
Tinct. Iodini ʒij.
Appl. Ad. Reg. Abdom. frequent.

The effect of the subcarbonate of potass in this case hitherto has been most remarkable, the circumference of abdomen being reduced thirteen inches, the ovarian tumour being now very distinct in the left iliac region. I do not, however, expect this effect will be continuous, nevertheless it offers a means of prolonging life with greater comfort in an aged person, or where the operation is otherwise not advisable.

MRS. WARD.

Mrs. Ward, Bell Street, Manchester, æt. 62, applied to me on the 13th November. The abdomen was enormously enlarged, fluctuation very distinct. I performed paracentesis abdominis, when 33½lbs. avoirdupois were discharged, thick, glutinous, and of a brownish colour, coagulable on the application of heat. After which I felt the ovarian sac with two large solid masses, situate in the right iliac region and one over the pubis, the appearance of the whole very much like the case of Mrs. Edge. As the age of Mrs Ward was more than I approved of for operation, and her constitution otherwise bad, I did not advise it, but substituted the potass mixt.; as in Mrs. Ormrod's case, at present it appears to check the refilling of the cyst. The reason I introduce this case is, to shew that ovarian diseases are perhaps more common than the profession has hitherto supposed, and I am inclined to believe very many of those obstinate cases of dropsy where there is frequent recourse to tapping, to be connected with ovarian disease; at least it would be well to pay a little more attention to the state of the ovaria after tapping, for if they *are diseased*, all the tapping in the world will never cure the disease.

CONCLUDING REMARKS.

After much reflection, I have no hesitation in stating my conviction that the extirpation of ovarian encysted tumours may be performed with comparative safety. And if the age be not too advanced, I believe the cases I have here given will fully prove that neither extent of adhesions, size of tumour, ascitic deposit, worn down constitution, nor peritoneal inflammation, should prevent extirpation being performed. The success of the operation is more than equal when compared with other capital operations in surgery. I would not advise, however, the peritoneal section so confidently in other tumours of the abdomen; still it is at all times a justifiable course where the patient earnestly requires it, and no other hope of prolongation of life presents itself. The exposure of the abdominal viscera, if the room be moderately heated, is attended with no bad consequences, nor yet a moderate loss of blood during the operation. The principal pain is confined to the first incision through the skin, and to the stretching of the pedicle whilst it is secured and severed. If the ligature is not drawn very tight, it will be much longer in coming away. I find it better *not* to let the interrupted sutures remain too long. I take every other out the third day, and the rest the day after, or at longest the 5th day. Thus much unnecessary irritation is avoided. Pain, after operation, is always controulable by a grain of mur. morphine. Some days after the pressure is removed from the abdominal viscera, there appears to be a tendency to diarrhœa, which, if not closely watched, and timely checked, may soon undo all the good that has been accomplished. Mere debility, arising *from the ovarian disease only*, before the operation, is more favorable than otherwise, and affords a good safeguard against peritoneal inflammation. I cannot conclude my remarks without correcting the statistical account of these operations as given in the preceding remarks rendered necessary by additional operations.

Large incision, 3rd., by Dr. Clay. Successful.—1 by Mr. Walne, do.—Total, 12 successful: 4 fatal.—Jeffreason, small incision.—1 by Dr. Stilling Cassel: fatal.—Total, 5 successful; 5 fatal

The above operations were for diseased ovaria only, in addition to which may be recorded two cases of anomalous and uterine tumours, of a very malignant character, which were attempted by the large peritoneal incision by myself, both of which proved fatal, the first from causes already mentioned, the last from the shock of the operation. I now leave the matter to the candid consideration of the profession, hoping those prejudiced against the operation, will examine fairly before they condemn. To those of more liberal feelings, (many of them men of the highest standing in the profession, who have kindly and considerately forwarded me their congratulations and approval of my humble attempts to improve pelvic and abdominal surgery) I return my best, my warmest thanks, as well as to the editor of the "*Medical Times*," for his courtesy in allowing me to occupy so many pages of his valuable journal.

THE MEDICAL TIMES.

SATURDAY, DECEMBER 3, 1842.

————Omnia Romæ
Cum pretio. Quid das ut Cossum aliquando salutes?

In every battle of men, says a German writer, there has been also a battle of principles—and, reasoning in his spirit on our struggles for hospital appointments, we are disposed to see in them, a conflict beyond that of the individual candidates—a conflict which, rising above the petty strifes of personal ambition and involving questions of social right, still more than private interests, presents to the impartial journalist (the earthly providence in these matters) the *dignus vindice nodus*, the justifying reason for interposition.

Impressed with the deep conviction that if ever there be an occasion in which merit alone should sway preference and support, it should be surely that in which a governing body has the appointment of an officer on whose scientific abilities, and conscientious attention to his duties, depend the most vital interests of a numerous portion of our suffering fellow-countrymen—it is with no little concern that we have to direct the public attention to the approaching election for the physicianship of Westminster Hospital, about to be made vacant by the retirement of Dr. Burne. It appears that there are already three candidates in the field. Dr. Kingston, a young person, hitherto unknown to the public—Dr. Basham, a gentlemen against whom the same charge cannot certainly be laid—and Dr. Robert Hunter, the eminent lecturer, whose name and fame were, last year, so adroitly enlisted by the Governors of the Hospital, in support of the fortunes of their *then* declining School. We will not attempt to disguise an *honest* personal preference in favour of the last-named gentleman—founded on the reports which have reached us of his scrupulous attention to his duties as a public lecturer—a trait but too rarely noticeable in our London lecturers: but, apart from any prepossession of this kind, it is impossible for any one who gives a moment's thought to the respective standings of the three candidates in the *scientific world*, to hesitate for a single instant about deciding who brings the highest—in truth, the *only*—real title to the appointment, and whose character promises to throw the greatest lustre over the institution benefitted by his labours. Yet if our assurances, received from various quarters, be correct, the candidate *least* likely of success, is precisely the gentleman most entitled to it. Merit would appear to be a quality far too subtle for the cognizance of the present system of hospital elections, which, accordingly, regulates its favours by a much more tangible and obvious standard—the length and strength of the candidates' purses. The decision, on the day of election, will convey to the poor patients but the Governors' decision on their physician's *pecuniary* superiority. Already golden instrumentality has been in full play. The prospect of a vacancy has softened—as by a miracle—the flinty hearts of stingy kinsmen, to the third and fourth degree. Ladies'-maids, retired serving-men, and insolvent tradesmen, have suddenly grown rich—and charitable as rich; and the Hospital List, in the short space of a month, shews two hundred new Governors moved by the soft impulses of divine benevolence to befriend an hospital, on whose existence depends, not the fortunes of some wretched invalids accustomed to misery, but, alas! much *worse*, those of some helpless, unprovided physician. The owner of these newly-purchased votes—whom rumour names as he who has most need of such extraneous appliances—we mean the youthful Dr. Kingston,—that gentleman will inevitably be the future physician, unless the other candidates are prepared virtually to bid a larger sum for the post. Dr. Hunter, we are told, will make no money-tender, and we may, therefore, place his appointment among those which are described by the Greek grammar as in the "*Paullo post futuro*" tense. Dr. Basham, judging from the unceremonious manner in which for the exciting cares of canvassing, he has been bilking his students of their purchased lectures, is not likely to be so very fastidious; and if the doctor's purse only equals his will, we shall no doubt have a neck and neck run between him and his more youthful competitor.

This is utterly, intensely, disgraceful—but we have so often enlarged on the iniquity of our hospital appointments, that we should hardly be excusable if we now dilated on the dishonour to the profession—the injustice to modest merit—the mischievous results to patients—and the general violation of the best rules of decency and morality, which the present system necessarily engenders. There may be, as some allege, something of fortune in every physician's practice—but there can be no doubt that in the long run, as in even the greatest game of chance, the greater skill must achieve the greater number of triumphs. Human life, it cannot be too well remembered, is the trophy of each success—as its destruction, or impairment, is the result of each failure: and it is not too much to say, that the deliberative choice of a secondarily-qualified attendant for the poor, is the Governors' sentence of death on an indefinite number of patients; and that the election of one ranking lower in qualifications, is a similar sentence on a still greater number of victims. But as we are told that it is preposterous to ask that the poor's health and lives—much less, the education of the students—should take precedence of the Westminster Governors' business-like anxiety to serve the protegé of a friend or customer,—we place these considerations before the candidates themselves, and ask those of the three before us, who are conscious of their secondary standing in science, how will they feel—the public, the while, frowning that distrust on them it ever shews to ill-acquired and ill-discharged responsibilities——as those untoward events, mildly called accidents, and the sure consequences in the long run of all incompetency, shew themselves in the fulness of time, in their calamitous, but well-scrutinized public practice? If this consideration be without power, let them reflect that the time when mediocrity could, in calm ease, and unscathed by public animadversion, work itself into profitable note, by undertaking perilous charges beyond the measure of its powers, is past. Moderate abilities are no crime with moderate pretensions; but when they hustle for an eminence at once undeserved and hurtful, they must not complain if sturdy common sense use his truncheon to keep them in order. Of one thing empty *pretenders* may be certain—they cannot court publicity and mischief, and escape ungibbeted by the *Medical Times*. The Babingtons and Hale Thompsons do not occupy *all* the gallows which we have constructed for the gang of moral convicts.

Two courses lie before the Westminster Hospital Committee of Management, accordingly as they mean to act a conscientious part on the one side, or a frank piece of profitable wickedness on the other. Either let them defer *sine die* the election, and in the meantime appoint a substitute whose name would retrieve the character, and whose labours would renovate the utilities of their charity; or else let them publicly announce for the benefit of their funds, the plain fact, without disguise, that their appointment is open to any man who will pay the most money for it. An advertisement in the style subjoined would draw a host of fresh candidates, and get a far better price for their appointment than even that Dr. Kingston advances.

"The Managing Committee of Westminster Hospital have a Physicianship to dispose of to the highest bidder. The only qualification required is hard cash (say 1000*l*.) a sum which if a little high in itself, is certainly small in reference to the elevation of the office, the absence of all other requisitions being considered. To a physician in his teens,

without practice, or to a superannuated valet, or coloured footman, this is a most eligible speculation: the first gentleman securing the advantage of unlimited practice on the poor, with free vivisections in their highest range (if required); and the second by the single preliminary of purchasing a German degree, being at once elevated into one of the highest positions of a learned profession, with the probable chance (if he be a man of tact and decorum) of a baronetcy and presidency of the College of Physicians.—Apply to the Secretary at the Hospital."

Illuc heu miseri traducimur!

There has been much — not to use a harsher term—disgraceful equivocation employed on the question concerning the examination of practitioners. The new practice, in reference to their admission, has been denied in plain terms, under the verbal shuffle that it is not a regulation. Now, the question *is* not, never *was*—whether a certain practice of known and acknowledged occurrence originated in a formal resolution, or was formally inscribed as a regulation on the College books. The question was, whether such a practice existed or not—and, its existence confessed, the whole matter in issue was ended. We say it existed,—so does Mr. Guthrie; and the subterfuge of denying the fact of a regulation in order to imply a breach of veracity on our sides, is nothing short of palpable and disgraceful immorality. In the new announcement which we last week shewed to be so peremptorily required—and which is now officially advertised, the College is made to stand out at once our accuser and its own condemner. There is not only a falsehood in the document, but there is a self-convicted falsehood — a transparent falsehood, which the council exposes in its own short statement. We are told first, that the reports published, and, with due respect to the priority of the College's own president, we willingly avow our share in publishing them; we are told that these reports are erroneous. Yet, what is the very next sentence? A resolution that gentlemen practising surgery before 1835 shall be admitted to examination, on producing proofs of such anatomical and surgical education as may be deemed sufficient by the Court of Examiners! Now, *practically*, what is the difference between this *regulation*—for we may now, we suppose, term it so—and Mr. Guthrie's, and our statement,—that practitioners were admitted to examination on their merits practically, without reference to the certificates that were customarily required? The *written* rule admits, it is true, a most mischevious discretionary power—a dangerous liberty of personal favouritism in the council; but, was not this the very vice we condemned in the council's past secret practice on this matter, and which Mr. Guthrie by his honest letter, and we by our public remonstrances, sought to correct? Every gentleman applying for examination will, of course, have had some education to justify his confidence; but, to restrict the examination to such gentlemen only as please the council, without any statement of a fixed standard of the sort of requisites that *must* please them, is an unwarrantable assumption of power for discreditable purposes, which the charter of the College can no more be made to sanction than can common sense or justice. The resolution, it will be seen, so far from opposing, supports our statement—that practitioners have been, and are, (we use Mr. Guthrie's words,) admitted to examination on their merits practically. The power of doing this, nay, the usage, is here distinctly claimed by the College; the only addition the examiners make to our statement is, to announce that they make such admissions dependant on their private caprices, their likings, and dislikings. They discard the principle of general uniform right, which we sought to connect with such admissions, and claim to act on the principle of the imperious harridan of the *Satirist*—" stet pro ratione voluntas." If they do prove us wrong on one point of fact by a *subsequent* arrangement, they do so with no increase of credit to themselves!

Will " The Royal College of Surgeons in London" allow us—*The Medical Times*—humbly to point out to them a rather remarkable *non sequitur* in their advertisement, which makes the document if not looked on as a piece of thin skinned duplicity, a very discreditable piece of literary composition? If their motive for taking the grave step of publishing be, as they say, to correct erroneous statements, how happens it that they set about it, not by publishing old regulations, but RESOLVING on something new? Was ever Hibernicism more complete than this notion of theirs that the establishment of a *new practice* is the natural mode of correcting the erroneous impressions existing on an *old regulation?* That the way to publicly explicate a given something, is to be silent on *it*, and explanatory on *something else?* Verily, verily, the wits of the badgered Examiners seem in a sad state of *bouleversement*.

Subjoined will be found a communication which throws additional light on this curious chapter in the council's history.

THE COLLEGE REGULATIONS.

(From a Correspondent.)

We again feel ourselves obliged to recur to the new "regulation" regarding the admissions of practitioners to examinations, which if not issued in the form of a printed proclamation, has been acted upon in a number of instances. The real state of the matter is this; Mr. Guthrie writes a letter to Dr. Hastings, stating (what was absolutely true) that practitioners are to be admitted on their merits.—Gentlemen have passed and are passing according to this new arrangement. Mr. Guthrie, with his customary courtesy, states that by "the *kindness* of the Court of Examiners, practitioners are, and have been, admitted to examination on their merits without reference to the regulations in force" — Kindness! *Contempt* upon the word!—A public governing body is morally bound to frame those regulations which shall most conduce to the good of the public. What has kindness, personal kindness, to do with the business? It is justice, not "*kindness*" which we and the profession demand. But this word kindness we fear lets "the cat out of the bag."

There is dissension in the Council of the College, part holding for the admission of practitioners upon their merits and part foolishly opposed to it; whereby (in case of one single instance of favoritism being proved,) they will render themselves liable to legal prosecution. The secretary has been inundated with applications, many of which he has for many days neglected to answer, keeping thereby some men of the highest respectability in the profession in a most cruel state of suspense. But after all this what has he summoned up resolution to state, so late as last week, in answer to an application made to him, by a member of the profession, regarding his admissibility for examination?—why, that "the arrangement referred to (admitting members on their merits) was unknown to the Court of Examiners, as no regulation of the kind has been made;" thus at once throwing the accusation of falsehood upon Mr. Guthrie's statement.

As Mr Guthrie is the great mover in our close body corporate, we should advise practitioners who are in doubt about their admissibility, to write to him; no doubt he will give them every information in coincidence with the information contained in his polite and highly important note to Dr. Hastings, read to the Provincial Medical Association in July last. In the mean time, what account are the Council going to render us of their conduct? The College of Surgeons presents a most perfect specimen of disorganisation, and this occurrence, more than any thing which has yet transpired, will hasten a thorough reform of this corrupt body:—it has confirmed their downfall as a close corporation.

Will it be believed, that one gentleman, in extensive practice, had his ticket of admission sent him by the secretary, with orders to present himself for examination on a certain day, and upon so doing was refused admission, although he had the order in his hand? If this gentleman is not an ignoramus indeed, he will bring them to a legal account respecting this business.

We wait with anxiety the proclamation of the regulation respecting practitioners now on the eve of being issued.

The Secretary of the College informed several persons, that pupils of old standing would not be admitted after January, according to the old regulations. This is now contradicted by some of the College Council, and affirmed by others.

ROYAL COLLEGE OF SURGEONS LONDON.

List of gentlemen admitted members on Friday, November 25th, 1842:—

F. H. Woodforde, J. Dowling, W. Roden, H. Aylward, S. S. Smith, J. J. Gray, C. J. Newstead, M'Collinson, J. Mahony.

Bequest.—Dr. James M'Adam, late President of the Medical Board, Bombay, has bequeathed in trust to the minister and heritors of the parish of Dundonald, of which he was a native, the sum of 1,000*l.*, to be invested in the public funds, and the proceeds to be annually distributed in blankets and coals amongst the poor during winter.—*Ayr Observer.*

REVIEWS.

English Patents for 1841. By A. PRICHARD, M.R.I. &c.

THIS is the promised sequel to the author's "List of Patents granted during the present Century." The increase in the number of Patents, and the importance of knowing what are "the goods" given us by the increased enlightenment of our times, as well as those which without offending law, we can claim full dominion over, both as regards creation and use, are reasons which make this neat list very acceptable. The arrangement appears to us good: the index of subjects is copious and of easy use, and we may shortly show our practical appreciation of the utility of Mr. Prichard's labours, by transferring to our pages that portion of them which has reference to improvements in chemistry and pharmacy.

Homœopathy Explained, and Objections Answered. LEATH.—To the reproach of public taste or private veracity, this *brochure* appears from the title-page, to have reached a circulation of four thousand. The most absurd systems, if they have enthusiastic followers, are not without useful fruits. Astronomy grew out of astrology—and we are indebted for some of our most potent agents in medicine and useful discoveries in chemistry to the honest delusions of the alchemists. So to the deception, more mischievous than either, homœopathy, are we indebted for some important new lights in pathology and therapeutics, but especially for the increased attention it has directed to the virtues of a good regimen, and the importance it deservedly attaches to the *vis medicatrix naturæ*. In producing, or tending to produce these results, homœopathy has performed its mission, and the sooner we now get rid of its trying *similia* on a dying man, whose vital powers are but already too overpowered by the *simile* he already groans under, and its practising on desperate cases by infinitesimal doses, the better for the credit of common sense, and the longevity of humanity. The author before us rejects, we see, altogether, *all external applications*, as blisters, moxas, setons, &c., on the score that they are mere *palliatives*, and as such, homœopathy (the off-hand doctor!) cannot condescend to use them! The book is more remarkable for its inconsequential reasoning, than anything else. Good faith and folly go hand-in-hand. The style is better than might have been expected.

ARGUMENTS OF SURGEONS AGAINST MESMERISM.

(To the Editor of the 'Medical Times.')

SIR,—Allow me a few brief observations on the arguments which (according to your report) were employed by several of the leading surgeons in London against receiving the case of amputation during mesmeric sleep, as having been really successfully performed. Dr. Moore requires affidavits. Doctor James Johnson requires more; he has implicit confidence in the veracity of Messrs. Topham and Squires Ward, but frankly denies any belief in the veracity of his own visual sensations. To say, *I will not believe what I see*, is absurd; to say, *I will not trust your deductions from what you saw*, is reasonable. Instance: I see the sun in the East, South, and West, respectively at morning, noon, and evening; deduction The sun revolves round the earth. Visual fact true, deduction false. People never said, we see the sun revolve round the earth; mesmerizers never say, we see mesmerism act. Let Dr. James Johnson mend his phrase. Mr. Alcock says that pain may be felt but not expressed. Is this a common case? It would be unfortunate if it were, as then, serious injury might be inflicted without warning being given. But it is at times very desirable, especially during operations, in which the patient's expression of pain, is frequently the greatest impediment to the operator's hand. Grant for the moment that pain was felt, but not expressed in this case; then by performing certain motions of the hand, we are enabled to prevent the nerves of any given patient from expressing pain. Theory apart here is a most useful result;—will Mr. Alcock reject it? The same remarks apply to several of Sir B. Brodie's cases; the case in which pain in the ischiatic nerve was expressed, contrasted with Mr. Topham's case, in which no such pain was expressed, tells wonderfully in favour of the latter; especially when no such pain was even *remembered*. Sir B. B.'s concluding argument is as follows. 1. The French Academy have made a report; I believe that that report is correct; Therefore I disbelieve in mesmerism. 2. None who disbelieve in mesmerism should receive Mr. Topham's case; I disbelieve &c.; therefore I should not receive &c. 3. (And this is the grand syllogism of all.) *all medical men should think as I do*; the Medico-Chirurgical Society is composed of medical men; *therefore*—The report of Mr. Topham's case should never have been read!! Dr. Blake finds *one* girl named Ross, was so silly and wicked as to feign mesmeric phenomena, *therefore*, *all* persons have feigned; therefore &c. in Mr. T's. case!!! Mr. Bransby Cooper knowing, I suppose, how all other effects are produced on the nervous system, requires that the mesmerizers should know how the effects they report have been produced. If Mr. B. C. would inform the world how any effect is produced on the nervous system, he would confer a benefit on society. Mr. Liston, who went to hear a case of amputation, hoped to have heard one of clairvoyance! What a pity it was that Dr. Syme gratified his hope. Dr. Arnott argues: I have known fifty ounces of blood taken from one patient, cause her not to express pain; no case in which other means have produced the same effect has presented itself to me; therefore—any evidence for other means producing such an effect is inconclusive! I could parallel this argument, but it is not worth while.

Conclusion.—Without stopping to consider the ideas for which the words, imagination, stoicism, heroism, philosophy, or what not are the representatives, the learned in surgery, pronounce that imagination, &c., are real agents, and do really produce these effects, and that, *therefore*, mesmerism is a delusion. Now Mr C. H. Townshend (*Facts in Mesmerism*) has long ago shown the true meaning of this argument, and its true bearing upon so-called mesmeric phenomena; and his conclusion, which I would have considered as the moral of this letter, is, in substance, the following: granted that imagination is the real agent, mesmeric passes are the external agents whereby the imagination is excited so as necessarily to produce these results; your "imagination" is only another line in the chain of causation, and one which we have clearly no occasion to take account of: we see the mesmeric passes, we see the mesmeric phenomena, and they necessarily stand to us in the relation of cause and effect. To disprove this, it must be shown, *not* that similar phenomena have followed from different causes in different circumstances, but that different phenomena have followed the same cause in similar circumstances. I am afraid, I have already occupied too much of your valuable space, and hasten to conclude.

SYLLOGISM.

---

*Extract from a Lecture on Percussion, with an Account of a New Percussion Instrument for Investigating the Diseases of the Chest. By C. J. B. Aldis, M.D., Lecturer on Medicine, at the Charlotte Street School.**

GENTLEMEN,—The subjects of percussion and auscultation, to which I am about to call your attention, are of great importance; for by employing these methods of diagnosis, you will be able to distinguish with precision, various diseases of the chest, and by their neglect, some important lesion of the lungs may be overlooked, which it will be your duty to endeavour to detect in order that you may apply the appropriate remedies. Besides when you recollect the frightful ravages, which pulmonary affections make among mankind; a fact rendering such diseases of the highest importance, I need scarcely say more to stimulate your attention to these means of diagnosis. I therefore hope that you will reflect upon the value of percussion and auscultation, the former of which will occupy us in the present lecture, and continually practice them.

Method of Percussing.—Some practitioners percuss with the fingers of the right hand, their extremities being in the same line and in a state of demiflexion, striking the chest in a perpendicular direction. Others employ four fingers of the right hand to strike—the fingers of the left hand applied to that part of the chest under examination. Piorry invented the plessimeter, a round piece of ivory to be placed on the chest and struck by the fingers for the purpose of preventing the pain, likely to be felt by some persons when the parietes of the chest are percussed. Subsequently, a light hammer having a leathern face, was brought into notice; the ivory plessimeter being struck with it by the right hand. More recently another instrument has been introduced; a handle is attached to the plessimeter, which is struck by a hammer held in the right hand.

Although percussion may seem a very simple operation, still it requires much practice, and many precautions are to be attended to. Now it is very requisite that you should produce equal sounds in comparing the opposite sides of the chest, for the slightest inequality in percussion will produce a difference in sound, and even on examining one side of the chest, we cannot place much reliance on unequal sounds.

About five years ago, I constructed a rough model of an instrument in wood with a hammer *attached* to it, having a spring handle, to be raised by the right hand, but I abandoned it in consequence of being in the habit of percussing the chest with my fingers. More recently, however, I made an outline of this instrument on paper, and thought that by means of a regulator, its elevation might be so managed, as to produce uniform sounds; for on raising the hammer it falls immediately, the spring handle touches the regulating screw, which is moveable, when it may be desirable to effect a greater or less elevation of the hammer, in order to produce greater or less uniform sound Messrs. Philp and Whisker, late Savigny, of St. James's Street, made the instrument for me.

Description of Dr. Aldis's Patent New Percussion Instrument.—The plessimeter is made of leather, moving upon a swivel, to adjust itself to the part. The percussor is attached to the stem of the plessimeter, and acts upon a joint; by pressing down the handle of the percussor, the spring throws the percussor down upon the plessimeter, the force of the blow being regulated by a screw.

* Delivered Nov. 28, 1842.

THE NEW PREPARATION OF IRON.

UNDER the name *Aqua Chalybeata*, Messrs. Bewley and Evans, of Dublin, have given us a new preparation of Iron, which possesses with the three advantages of chemical permanence, solubility, and the absence of that constipating tendency which so much interferes with the utility of the common preparations, an agreeableness of taste accompanied by a brisk effervescence which makes it as agreeable as Champaigne.

The report of an analysis by Dr. Ure, has been submitted to us which after a very satisfactory statement, is concluded with the expression of the

Doctor's belief that this preparation promises to form the *most* efficacious of chalybeate medicines. The opinion of Professor Brande is thus given in its favour.'

London, November 24, 1842.

I have examined Messrs. Bewley and Evans's new Chalybeate water, which is a solution of a citrate of iron in water highly impregnated with carbonic acid. I think that this solution will prove a valuable addition to the materia medica, and that it is likely to agree with the system, when many of the other chalybeate preparations are inadmissible: while its effervescent property and agreeable flavour render it well adapted for very delicate stomachs and for administration to children. (Signed)—Wm. Thos. Brande.

GUNSHOT WOUND.

Secondary Hæmorrhage and Ligature of the Subclavian Artery.

By William Smith, Esq., Surgeon.
(For the 'Medical Times.')

Private Mahoney, of the sappers and miners, of the British Auxiliary Legion, was wounded during the assault and capture of Irun, on the 17th of May, 1837, by a musket shot, which entered immediately under the left clavicle. In this position, passing in a straight line, it fractured anteriorly the second rib; and entering the cavity of the pleura, penetrated the superior lobe of the left lung; from thence proceeding backwards, it fractured again the posterior portion of the second rib towards its spinal attachments. After this, it pierced the body of the scapula; and coming in contact with the integuments of the back, its course was diverted downwards, until it finally lodged in the subjacent cellular tissue, below the inferior angle of the fractured bone.

For the first two days after the receipt of the injury, cold applications were applied to the situation of the wound; and this local treatment was accompanied by venesection, and saline medicine of a laxative nature every third or fourth hour. There being no wound externally, on the posterior part of the chest, I began to suppose that the bullet must have lodged in the cavity of the pleura, until on the morning of the 19th, when the patient complained to me of slight pain at the inferior angle of the left scapula. On examining the part complained of, I felt a round hard substance pretty deeply embedded under the integument, which I had no doubt was the bullet. I therefore made an incision directly through the skin, down upon the foreign body, which was extracted without difficulty.

Up to the 21st, everything seemed to proceed favourably; indeed, so much so, that without examination, any injury of the pleuritic cavity from the present symptoms could not have been supposed. At this time, however, the symptoms of inflammation became apparent, and much constitutional disturbance supervened. The pulse became full, strong, and accelerated, the breathing laborious, the urine high coloured, and diminished in quantity; whilst at the same time there was considerable pain in the superior portion of the left lung, and the situation of the wound. The local and constitutional symptoms of incipient pneumonia were present. On the presentation of the above, venesection was performed to the extent of lbij. which produced much relief. The bowels immediately after were freely opened; and the symptoms progressed favourably until the forenoon of the 24th. On that day about 11 a.m. I was informed by the ward orderly, that Mahoney was bleeding profusely from the wound on the anterior aspect of the chest. On receipt of this information I proceeded immediately to his bed, and found the orderly's statement correct. I examined the wound, and removed several clots of blood, which filled it in part and shewed the hæmorrhage to be of a venous character. On introducing my forefinger along the course of the wound, the subclavian artery could be distinctly felt pulsating under the clavicle; and it was my impression at the same time, that the hæmorrhage proceeded from the subclavian vein. I now applied a few folds of cloth soaked in cold water to the shoulder; which had the effect of stopping the hæmorrhage almost instantaneously; and as the quantity of blood lost was not great, and as it was also of a venous character, I reported the case to staff-surgeon Gannon, hoping there might be no more cause for alarm. All seemed, after arresting the hæmorrhage, to go on favourably with Mahoney; the untoward symptoms of pneumonia with which he had been previously seized, had been apparently much benefitted by the accidental hæmorrhage; and it was thought, that a gun-shot wound of the pleuritic cavity in this case had a fair chance of being enumerated amongst one of the cures. Our hopes, however, were not doomed to be verified. On the morning of the 26th, at ten o'clock, the hæmorrhage again resumed, perhaps to the extent of one pound, before it was arrested by cold applications similar to those used in the first instance. A brief consultation was now held on the case; the medical officers present, being staff-surgeon Gannon in charge, assistant-surgeon Brery and myself. The case was a puzzling one. There was no doubt but that the subclavian vein had been originally injured, and now ulcerated; and such being the case, it was difficult to say whether or not, the subclavian artery was altogether safe. Unless, however, the hæmorrhage should be arrested, there could be no chance of the patient's life being saved; therefore a doubtful remedy was resorted to, in preference to none at all. To tie the vein would have been a novel, and according to surgical practice, a dangerous proceeding; and even if it should have turned out successful in itself, it was very questionable whether the artery was uninjured. For this reason in order to meet the hæmorrhage at all points, I proposed, in case it should recur again, to tie the subclavian artery at the point where it passes over the first rib. To this proposal, after many doubts on the success of the measure, Messrs. Gannon and Brery consented; provided nature should seem determined to show the patient no mercy. According to our resolution the opportunity for operating was not long delayed. On the following day, the 27th, about 11 a.m., the hæmorrhage recurred; and the operation was proposed by me, and assented to by the patient, in a few minutes.

The patient was not removed from his bed, but simply placed in the most favourable position with pillows; and with the able assistance of Mr. Brery, I began my operation. An incision was made above the clavicle, through the skin and subjacent cellular tissue, commencing at the clavicular attachment of the sterno-mastoid muscle, and extending on a line nearly parallel to that bone, outwards to the distance of nearly three inches. From the sternal extremity of this incision, a second was made upwards, on a line parellal to the external margin of the sterno-cleido-mastoid, to the extent of two inches; and the angular flap was dissected backwards from the union of the two incisions. The cervical fascia was next cut through; and the subjacent adipose substance pressed aside with the handle of the scalpel, until the scalenus anticus made it appearance, crossed by the omo-hyoid muscle. The cervical plexus was then pressed gently backwards; and I placed my finger anterior to this, upon the first rib; but contrary to my expectation, could neither feel the artery nor its pulsatory motion. This circumstance annoyed me the more, as I deemed my incision sufficiently large and clear of blood; but being certain I was in the usual situation of the artery, I took Weiss' spinal aneurismal needle, and placed its point upon the superior margin of the rib, anterior to the plexus, and as I judged, behind the artery. Then pressing it firmly forward a few lines, taking care to keep its point still in contact with the margin of the rib, I turned the same upwards by a rotatory motion of the handle; and the former made its appearance, elevated near the centre of the wound. On keeping the handle in the same position, and pulling the needle gently upwards, I discovered the subclavian artery lying on its spiral curvature. I now made certain that this was the case, by pressing firmly between my fingers and thumb, the vessel and the needle together; this proceeding immediately stopped the pulsation in the wrist, which before, was free and perceptible. The vessel was now tied, and the wound closed without the loss of one ounce of blood during the operation.

The patient stood the operation well, and for the first six hours, complained of nothing particular, save a slight numbness of the left arm, fore-arm, and hand. At the end of this time, however, his breathing became somewhat laborious; and this untoward symptom continued to increase in such a manner as to prove, that the termination of the case would be fatal. The patient died twelve hours after the performance of the operation. After the application of the ligature, however, the hæmorrhage was completely arrested; and had the lung been less injured than it presented itself on dissection, the chances would, there is every reason to believe, have been in favour of the patient.

Sectio Cadaveris.—twelve hours after death.—The pleura costalis and pulmonalis were firmly united by old adhesions, on the left side of the thorax; and the superior lobe of the left lung was penetrated by the bullet from before backwards. The second rib of the same side, was fractured anteriorly aad posteriorly; and spiculæ of its anterior portion were found imbedded in the parenchyma of the lung. For a considerable distance around the wound, the lung presented the appearance of sphacelation. The subclavian vein was ulcerated, and presented a ragged opening communicating with its canal, in the situation of the wound, below the clavicle, from whence the blood had issued. The coats of the artery at the same point were inflamed, and presented a black spot in the centre of the inflamed surface. The other viscera were healthy. The artery was sound at the point on which the ligature was applied.

157, Bishopsgate Street, Without.
October, 26, 1842.

PERISCOPE OF THE WEEK.

Statistics of Phthisis.—Dr. Briquet, of the Hopital Cochin, in Paris, gives the following as the result of careful observations:—Of 609 individuals who had died in the hospital throughout the years 1838, 1839, and 1840, 182 had succumbed under phthisis, of whom 91 were males and 91 females; while 427 (204 male and 223 female) died of other diseases. It would appear, therefore, that taking into account the whole number of individuals dying in the hospital, the mortality from phthisis was about one-tenth greater among males than females.—Of 98 phthisical patients, 30 were descended from parents who had suffered with the same disease; and out of 88, 47 had been brought up in towns (24 in Paris) and 41 in the country, hereditary predisposition having been as frequent among the

latter as the former.—24 patients were tall, large built, and corpulent, 9 tall and slender, 15 diminutive and meagre; the rest were of medium height and make. 33 were naturally of a robust, and 21 of a feeble constitution; and the rest were of intermediate vigour.—As to temperament, some curious particulars were remarked. Out of 65 males, 29 were dark complexioned, with dark hair; and 36 were fair, 4 of whom had white, 4 yellow or reddish, and the remainder chesnut-coloured hair. Of 37 females, 8 had dark hair and complexion, and 29 were fair, nearly all having hair of a chesnut hue. Out of 75 male patients not attacked with phthisis, 29 had both the hair and skin dark, and 46 were of a fair complexion, 12 having light, and the rest chesnut-coloured hair; while of 50 females, also not phthisical, 26 had dark skin and hair, and 24 a fair complexion, 2 having yellowish, 4 white, and 18 chesnut-coloured hair.—In 63 out of 70 patients, the extremities of the fingers were more or less abnormally developed, or the nails curved (*scutiformes.*) In 85 cases the conformation of the thorax was particularly noticed: in 37 it was well formed; in 48 altered more or less from its natural shape.—Out of 94 patients, 31 were little subject to catarrhs, while the remainder were more or less liable to take cold readily, and 9 had been accustomed to a cough from infancy. Those born of phthisical parents seemed not to be more liable to take cold than others. Of 37, 15 were particularly apt to suffer discomfort from a cold atmosphere; but here again, those of phthisical descent were not more liable than the rest.—As to the age at which phthisis usually makes itself manifest,—in three-fifths of the cases, it is, according to M. Briquet, between the ages of 20 and 35 years; and in most of the remaining cases, between 35 and 50 years of age. The mean age at which the patients descended from parents subject to phthisis were first attacked, M. Briquet found to be 27; while in those in which the disease was not proved to be hereditary, 31 years of age was the mean of its first appearance. The distinction of sex appeared to make no difference in this particular. Of 98 cases, 30 supervened during Dec., January, and February; 24 in March, April, and May; 20 in June, July, and August; and 24 in September, October, and November.

New Means of Vomiting.—Dr. Marshall Hall recommends the following means of producing vomiting in cases of poisoning. It frequently happened that we were called urgently in such cases without possessing an emetic, an antidote, or the stomach-pump. What was to be done? Call in aid the excito-motory principle. We see the sailor lying across with the stomach pressing on the yard-arm, yet he does not vomit. The cardia is closed, effectually closed, against such pressure. On the other hand, we often see a patient, especially when under the influence of a narcotic poison, attempt to induce vomiting by irritating the fauces, in vain. In the latter case there are, however, frequently ineffectual heavings and attempts to vomit. Use, then, these efforts to remove the poison. During these efforts the larynx is closed and the cardia opened; it is the insufficient action of the abdominal muscles which renders the attempt to vomit abortive. At this moment, if we apply forcible pressure to the abdomen, the stomach is emptied. That pressure, augmented at intervals, produces the effect of pressure applied over the distended bladder, after introducing the catheter: the stream is proportionately augmented. "I have seen," says Dr. Hall, "when the stomach-tube has been introduced, a similar effect. The tube has irritated the fauces, and the cardia has been opened in con equence, whilst an effort of vomiting has been induced. This, though slight, has caused the contents of the stomach to pass both through and by the sides of the tube, and external pressure has produced the same effect as before. It is this *simultaneous* irritation of the fauces and pressure on the abdomen, that I propose for the treatment of poisoning. It will succeed, I believe, in those cases in which emetics would succeed. It is always at hand, the stomach-pump being reserved for those cases which are strictly appropriate to its use, or to complete what this has left imperfect. The patient may be placed leaning with the stomach over a chair, protected by a pillow, whilst the fingers are introduced to irritate the fauces."

Diseases of the Heart.—According to M. Tanchon, tumours of the female breast increase with the progress of civilisation. Thus, in the department of the Seine, during the year 1830, 668 persons died of cancer; in 1840 no less than 889, being an increase of from 1.96 to 2.40 per cent, on the total mortality during that period of 382,851 individuals. In Paris, the number of deaths from cancer in 1830 was 595; in 1840, 779, giving a mortality of 2.51 per cent on the deaths; while in the rest of the department the deaths were—in 1830, 73; in 1840, 110; or 1.63 of the total number.—M. Tanchon proposes various means for arresting the progress of tumours of the breast. He speaks strongly against excision and the use of caustic substances. Amongst other means, he proposes pressure, together with the use of the following substances, which are applied in little bags:—Ioduret of potassium five parts; powdered sponge, ten ditto; hydrochlorate of ammonia, forty ditto; hydrochlorate of sodium, ten ditto; or a powder composed of powdered sponge, twenty parts; nitrate of potass, one ditto; Florence iris, one ditto. Thirty patients were treated in this manner, and all seemed to be very considerablyimproved. In some cases the mammary gland disappeared altogether; in most only a remnant of it was left, although several of the patients had been advised to undergo an operation before the treatment had been commenced; it was not found necessary to have recourse to the knife in any instance.

Inoculation of the Measles—Dr. M. Von Katona, of Hungary, after renewing the experiments of Dr. Howe and Speranza on this subject, speaks highly of the value of inoculation in dangerous epidemics. He says, in 7 per cent, of the cases the inoculation failed, but the remainder took the disease, which ran its course in a very mild manner, strikingly different from the disease as it prevailed at the time. In no instance was the disease thus communicated fatal. The inoculation was performed in the same way as for small-pox, by taking some fluid, mixed with blood, from underneath the efflorescence. A red areola formed round the point of insertion and then gradually declined. About the seventh day, fever and the usual premonitory symptoms of measles set in; on the ninth or tenth day after inoculation, the eruption appeared and ran its usual course but in a very mild manner. On the fourteenth day the fever commonly declined, and on the seventeenth (or seven or eight days after the eruption) the patients were convalescent.

Treatment of Rheumatism by the Sulphate of Quinine.—Twenty-three patients labouring under acute rheumatism were submitted by Dr. Briquet, Paris, to treatment by the sulphate of quinine, they were not selected cases. During the first day of treatment the patients took (according to sex, age, constitution, &c.) from four to five, or six, scruples of sulphate of quinine in eight ounces of gum emulsion. The mixture was given in tea-spoonfuls every hour, so that the whole was taken within the twelve hours. On the following day the same dose was administered in the same way. On the third day, as the symptoms were almost constantly greatly relieved, the dose was gradually reduced by one or two scruples daily. The period of treatment was generally six to eight days, during which the patients took from an ounce to an ounce and a quarter of sulphate of quinine. The medicine was usually given in the form of mixture; but when the patient expressed any dislike to it, the form of powder or pills was selected. The auxiliary means employed were a decoction of borrago for drink, opiate poultices, and absolute rest. Of the twenty-three patients, fifteen were males, nine females, from twenty to thirty years of age; one-third were strong, the remainder weakly and of lymphatic constitution More than one-third had been subject to rheumatism, and nearly one-fourth had symptoms of chronic pericarditis. On an average, when admitted into hospital, the pain and swelling of the joints had existed for from three to four days. They all, with one exception, began to take quinine on the day after admission; at this period, in two-thirds of the cases, the complexion was a straw-yellow colour; tongue white and moist; great thirst; no appetite; in a few, diarrhœa and cough. In about a fourth there were evident signs of recent or chronic pericarditis; in four the pulse was 60 to 65; in thirteen, 70 to 80, or 90; in six, from 110 to 120. In all the presence of rheumatism was indicated by severe pain, with tumefaction and tension of the joints; heat and redness of the skin, and enlargement of the neighbouring veins. In some the inflammation was of a phlegmonous character; in others there was merely hydarthrosis; in others muscular pains The number of points simultaneously attacked varied from four to twelve. After twenty-four hours treatment all the patients,except four, experiencedveryconsiderable relief of their symptoms. In one the local symptoms completely disappeared after forty-eight hours; and the same occurred in fourteen patients during the course of the third day. In six patients there was no sign of local disease on the fourth day, so that at this period all the patients, except two, were cured; of the latter, one was a young female labouring under general acute rheumatism, which persisted up to the seventh day; and the other, a young man who refused to continue the treatment, on the fifth day. By complete disappearance of the symptoms, M. Briquet means complete absence of pain and tumefaction, with restoration of the movements of the affected joints. It was not observed that the date of attack, when the treatment was commenced, had any influence on its efficacy. A relapse took place in two cases only; and the only example of failure was one of rheumatic affection of the wrist-joint

Nature of Tubercles.—The elements of the blood, says Mr. William Addison, visible by the microscope, without any manipulation, are—1st, The red corpuscles; 2d, the colourless corpuscles; 3d, molecules and granules in the interior of the colourless corpuscles; 4th, similar molecules and granules isolated in the liquor sanguinis, and independent of the corpuscles; 5th, the fibrine, which may be seen by the microscope coagulating in the form of delicate cylindrical fibres, having a diameter even less than that of the molecules. The fi-

brine does not form globules or corpuscles of any kind. Molecules, granules, and colourless corpuscles, enveloped in a net-work of fibrinous fibres or filaments, with variable quantities of entangled serum, form the entire mass of the buffy coat of the blood. The phenomena displayed on the addition of liquor potassæ (Brandish's alkali) to the blood corpuscles are very remarkable; the first effects of the fluid are very rapid and energetic; after a short time, by following the directions given in the paper, the alkali may be observed slowly diffusing itself among the corpuscles. The red corpuscles may be seen to explode and disappear instantaneously, or to burst open gradually, and discharge their contents, and many singular changes of form may be witnessed. The colourless corpuscles may be completely and slowly dissected by a proper application of the liquor potassæ—all the stages of the process and the number and nature of their contents may be readily seen by the microscope. For this purpose, a drop of the liquor sanguinis from the surface of buffy blood is removed by the point of the finger, and transferred to a slip of glass, previous to coagulation; it should be spread out on the glass, and the liquor potassæ cautiously added from the point of a penknife or a lancet, while the corpuscles, without any covering, are under examination. This manipulation, with a little practice, may be readily accomplished with one of the small upright french microscopes, and by moving the slip of glass gradually forward, the progress of the alkali may be watched for some time. Rapid changes take place; molecules and granules are developed in the interior of the corpuscles, which enlarge by imbibition, and then dehisce or explode, the molecules and granules pouring out of them in great numbers; if the alkali be acting weakly, the molecules swell to granules, and the granules enlarge previous to their final disappearance by dissolution in the liquid. Pus corpuscles differ in no respect from the colourless blood corpuscles, except only as they are altered in size and appearance by exhaling their own contents, or by imbibing the fluids with which they are associated. Water and the dilute acetic acid cause them to enlarge, developing the molecules and granules in their interior. The effects of the liquor potassæ upon them are very singular and instructive. On the application of this liquid, the corpuscles immediately begin to enlarge by imbibition; a great number of granules become exceedingly conspicuous within them; finally, they burst open or explode, and the granules are dispersed around. Several cases and experiments are minutely detailed in corroboration of the foregoing statements, from which the two following are selected:—*Case of Shingles.*—One of the clear transparent vesicles was opened with the point of a lancet, and a great number of colourless blood corpuscles was found by the microscope in the fluid. Many of them exactly resembled the corpuscles in the blood; others appeared a little shrivelled, and a few were remarkably large. All of them contained molecules; the large ones had several bright granules, which, on close inspection, were evidently moving within them that is, the granules disappeared in one part of the corpuscle, and became visible in another. This was repeated several times during the observation, apparently from the working ("*writhing*") or undulation of a fluid, which, by alternately dividing and coalescing, and then again dividing, formed the granules, which were sometimes visible at one spot, and then at another. The author has seen similar phenomena in the inner vesicle of the red corpuscles after the addition of a drop of gum water.—A little water was now added to the corpuscles from the point of a lancet: after a few minutes the shrivelled corpuscles became quite plump. Liquor potassæ was afterwards added very cautiously in the same way, and the corpuscles, one after another, dehisced. At first they gave a sudden jerk, and enlarged to twice or three times their former dimensions, displaying the granules in their interior; and then they burst open by a kind of explosion, each corpuscle discharging about twelve large granules, which were gradually dissolved.—*Case of troublesome catarrh (hay-fever.)* Copious discharge of clear transparent fluid from the nostrils; a perfectly limpid drop of the mucus was examined by the microscope, and I was somewhat surprised to find in it a great number of colourless corpuscles, resembling the colourless corpuscles of the blood. There were, indeed, corpuscles of all sorts, forming a complete series, with gradual transitions, from the colourless blood corpuscles through all the forms and varieties of pus corpuscles, up to large, round, granulated corpuscles and epithelium cylinders. My astonishment was great when I found most of these corpuscles provided with vibratile cilia in the most active state, so that some of the corpuscles were actually moving about by their means; and not only were the cilia in motion, but the molecules and granules in the interior of the corpuscles were in a very active state; they could be seen rapidly shifting their position within the corpuscles.—I examined no less than six different specimens of the mucus from the same individual, and I always saw a series of similar objects.—*Case of Cancer of the Breast* (existing some years.)—Arm œdematous; the back of the hand had been punctured some weeks ago to relieve the swelling, and a serous fluid has been discharged from it ever since. The author frequently examined this fluid by the microscope, and always found in it a fibrinous coagulum, and corpuscles resembling in every particular the colourless corpuscles of the blood, somewhat altered by shrivelling. When the arm was cool and free from pain, the fluid discharged was perfectly limpid, as colourless as spring water, but corpuscles were found in it; and after standing ten or twelve hours, a delicate but almost invisible net-work of fibrine could be drawn out of it with the point of a needle. Sometimes the arm, without any obvious cause, became much more red, swollen, and painful, and then the discharged fluid had the appearance of ordinary serum; the number of corpuscles was much increased, and the coagulum was more dense. On the addition of water the corpuscles swelled out and enlarged; with liquor potassæ they burst open, discharging large granules. From the result of this and other experiments, it is evident that the serous fluids effused in dropsies differ from the serum after venesection; they contain fibrine and corpuscles. The fluid at the surface of inflammatory blood is the liquor sanguinis, highly charged with molecules, granules, and colourless corpuscles; it is a strong solution of fibrine. The limpid fluids discharged by œdematous swellings are of a precisely similar nature, with a less quantity of fibrine and a less number of corpuscles; the varieties of coagulable lymph are intermediate between the two extremes. All abnormal discharges, and all the varieties of serum and coagulable lymph, are modifications of the liquor sanguinis—stronger or weaker solutions of fibrine. All the varieties of pus and lymph corpuscles are more or less altered colourless corpuscles altered either by imbibing and growing larger, or by exhaling, shrivelling, and becoming less. In fact, all abnormal products are effusions, and not secretions.—The foregoing experiments (here briefly stated) are brought forward to strengthen the conclusion which it is the author's object to establish,—viz., that all secretions take place in the interior of granulated vesicles or cells, not by transudation from one tube (a bloodvessel) into another (a duct;) consequently that "tubercles in the lungs," "tubercular infiltration," "hepatisation," and "pus," are not secreted products, but simply the elements of the blood effused by an excessive "vital turgescence" (or inflammatory action,) having their peculiar characters determined by the texture and function of the structure, and by the amount of activity of the turgescence.*—A singular fact is stated with regard to the animalcules; it may be witnessed in all of them by the application of liquor potassæ (which the author calls his dissecting fluid.) It penetrates the transparent tunic composing the body of the animalcule, by imbibition, and soon causes it to burst open or explode, precisely in the same way as the colourless blood or pus corpuscle; and the so-called stomachs of the creature are forcibly discharged, or thrown out one after another, thus becoming objects for minute microscopical scrutiny. The stomachs (?) swell and burst in like manner, precisely as the granules discharged from the lymph corpuscles of the frog, or from the pus corpuscle. These stomachs the author believes to be granulated vesicles, performing their functions by imbibition, and not by assimilating or digesting food voluntarily taken. The vital powers of the animalcules are totally inefficient in opposing the imbition of the poison, and their stomachs may be seen enlarging in the interior of the body prior to the rupture of the integument.

The Abdominal Aorta Tied.—The following statement is derived by a correspondent from an article in the *Journal de Commercio*, August 7, 1842:—"On Friday, July 5th, at No. 13, Rua das Violas, the abdominal aorta was tied, for the first time amongst us, immediately above its bifurcation, without doubt the boldest operation in surgery, and carried into effect in England only by Astley Cooper and James, without any favourable result. Nevertheless, the patient, A. M. Cardozo, seemed to be overcoming the terrible consequences that it was supposed would follow. The operator, was Dr. Candido Borges Monteiro. For about a week after the operation the patient was seemingly getting better, but they could not consider him out of danger for at least twenty days,"—not to live, however, for he died on (I think) the 15th. The body was taken next day to the School of Medicine, and examined by the operator, in presence of a number of medical men, when they found that everything had been rightly performed, the case only affording another proof that the result must necessarily be fatal.

MEDICAL NEWS.

The Numerical Method.—M. Trousseau, in his recent public "*Discours*," thus speaks of this system:—"The numerical method, which has for its base, statistics, and which was first introduced into 'Hygiène' by Parent du Châtelet, was applied to the study of pathology and therapeutics by a man equal to all praise. It recognizes the absolute power of figures. The physician must impose silence on the imagination; he analyses, counts, and registers ri-

* The author refers to Mr. Goodsir's paper, and corroborates his opinion with respect to secretion.

cidly results,—he does no more, no less. It applies to medicine the doctrine of probabilities in all its rigour. I make this no matter of reproach; for we cannot systematize without counting—but I do reproach it that it *only* counts, that it counts too much, too long—and ever—and excludes all *mind* in things. It is the scourge of intelligence: it makes a physician a counting clerk. Its boast, the exclusion of the intellectual faculties, is its condemnation." He goes on to remark, that in effect the numerical system is but the system usually followed, decked out with a parade of figures instead of terms equally expressive (*ex. gr.* 90 in 100, instead of the old term "almost always," &c.), that the observations are all conflicting, varying in different places with every observer, and considers that its principal utility are the habits of exactitude it encourages.

A Harmless Specific.—An old physician is now living in Paris, who unlucky in practice, set about establishing a patent medicine. Restrained somewhat, if not by a sense of decency, by one of morality, he determined on using a remedy which, if it did no good, should at least do no harm—and therefore fixed on "distilled water," which, under a grand name, was duly puffed; and became a medicine of very general requisition for an infinite variety of maladies. The certificates that poured in upon the surprised inventor, were beyond number, and spoke of cures the most marvellous, performed in the most marvellously short time. But the greatest wonder of all was, the revolution produced in the physician's own opinion; for after making an ample fortune by the medicine, he continues to sell it (after the need that led to its introduction is gone) in a conscientious belief that it is in truth a sovereign remedy, the salts and other foreign principles in the water in common usage, being now thoroughly believed by him to be the source of two-thirds of chronic maladies. M. Trousseau, who relates this anecdote, deduces from it a lesson of greater reliance on the curative powers of nature, especially when untampered with, insinuating with the satirist, that our business in general is but to amuse the patient, while we allow nature to cure him.

A Journal of English and Foreign Medicine and Medical Affairs

No. 168. Vol. VII. LONDON, SATURDAY, DECEMBER 10, 1842. PRICE FOURPENCE. Stamped Edition, 5d.

For the convenience of Subscribers in remote places, the Weekly Numbers are re-issued in Monthly Parts, stitched in a Wrapper, and forwarded with the Magazines.—Orders for the Stamped Edition (10s 10d. per Half year, Post-free in advance,) are received by any Book-seller or Newsman, or may be directed to J. A. Carfrae Esq., at the Medical Times Office, (late Lancet Office), London

SUMMARY.

LECTURES ON CHEMISTRY.

By JOHN SCOFFERN, M.D., Lecturer on Chemistry, at the Aldersgate School of Medicine.

I purpose in this lecture, examining some of the important relations which obtain between the three agents , heat, electricity, and magnetism.—This is a subject of intense and still increasing interest, but its connexion with the science of chemistry is not sufficiently intimate to warrant our devoting more than one lecture to its consideration. Let us begin by examining the connexion which exists between electricity and heat,—whence has arisen the term "*thermo electricity*."

If a ring of any metal of equal size, and homogeneous composition, be heated at one particular point, no disturbance of electric equilibrium takes place ; but if its size be not equal in every part, or if previously to its formation into a ring, a knot had been made on any part of its future circumference, then electricity would have circulated from the point heated to that part where there might exist the least amount of obstruction. If instead of employing *one* metal with this knot or enlargement, two metals be employed, electric disturbance, under the same circumstances of heating, again results, and in proportion as the molecular constitution of the metals vary, so does the intensity of the results increase. Now, as a general rule, the molecular constitution of metals is such that they crystallize in the cubic or tessular system ; antimony, however, crystallizes in rhombohedrons, and hence is capable of forming a thermo-electric combined with almost any other metal ;—bismuth being generally preferred. In order to form a thermo-electric combination the two metals must be soldered together at one end, and in order to develop the usual results, heat must be applied at their point of juncture, when electricity will be determined from the antimony towards the bismuth.

Such a thermo-electric apparatus as I have described is far too devoid of power for the development of any brilliantly marked results, but the ingenuity of Nobili devised a compound instrument which stands in the same relation to the simple one that the pile of Volta did to the powerless instrument of Galvani. The instrument to which I allude, consists of several combinations of antimony and bismuth, instead of one of the metals, being soldered together at opposite extremities, and separated from each other by some insulating materials, (I believe in practice, the substance employed is plaister of Paris,) the minute interstices of which are filled with melted lac. Without going more into detail relative to this or other thermo-electric combinations, suffice it to remark, that when heated at the points where the two metals join, there is set up an electric current, which yields under proper conditions a spark and other results, fully establishing its identity with electricity from other sources.

A slight examination of these facts cannot fail to enlarge our ideas of natural electrical excitation. We know that the crust of this planet is composed of numerous materials placed in opposition with each other, and granting that any source of heat be applied in any unchanging direction—there will be generated a current of elasticity unchanging in its direction too. From this it would not be unreasonable to suppose, *à priori*, that, inasmuch as the earth is heated in the direction of east to west by the Sun's rays, that an electric current is also set up in that direction ;—that such is the case, is in accordance with observation and experiment, as we shall presently see. I wish to impress this most firmly in your minds, inasmuch as it is intimately connected with Ampère's theory of terrestrial magnetism. With this passing notice, I must dismiss this subject to enter upon the consideration of electricity and magnetism, as regards their mutual relations to each other.

The early electrical experimenters were struck with the similiarity which obtained between some of the effects of their agent, and those of magnetism: indeed, the first detailed account of electrical attraction and repulsion, was given in a treatise on magnetism; and a kind of vague idea soon after became prevalent, that the electric attractions and repulsions were identical, although experiment failed to afford the necessary demonstration. It is a very well known fact, that flashes of lightning have, on several occasions, produced variation in the magnetic direction. Several authentic instances of this effect are on record ; for example—it is related in the *Philosophical Transactions*, Vol. XIV., p. 520, that the ship Alexander, when in lat 48 deg. encountered a violent thunder storm. The mast was struck by lightning, which also reversed the poles of all the compasses in the ship; —a change which was not discovered until the ensuing night, when the stars appeared, and it was found that they had been steering in an opposite course to which they intended. It is also stated, that in one of the compasses the end which had before pointed to the north now pointed to the west. Again, another instance is mentioned of a flash of lightning having passed through a box containing a great quantity of knives and forks, melting some, and scattering the rest about the room ; those which remained were converted into powerful magnets. In imitation of these phenomena, strong shocks were passed through steel and iron bars, by means of electrical batteries, by which treatment, magnetic effects were certainly produced ; but the results were so capricious and irregular, so little under the operator's control, or in accordance with known laws, that they led to no useful deduction.

D'Alebard imagined that electric currents imparted northern magnetic polarity where they entered, and southern polarity where they left an iron bar ; and this result was presumed to be quite independent of the needle's position, with regard to the magnetic poles of the earth. Wilke, on the contrary, imagined that he could trace a connection between northern polarity and the place where the electricity left ; thus you will see how little, up to this period, were the opinions of experimenters in accordance.

In the year 1774 the following question was proposed by the Electoral Academy of Bavaria, as the subject of a prize dissertation. Is there a real and physical analogy between electrical and magnetic forces? and, if such an analogy exist, in what manner do these forces act upon the animal body? The essays received on that occasion were collected, and published ten years afterwards by Professor Van Swindon, of Franeker, the author of one of the essays, for which the prizes were awarded. The conclusion to which he arrived after a long and elaborate discussion on the subject was, that the similarity between electricity and magnetism amounts merely to an apparent resemblance, and does not constitute a true physical analogy ; whence he infers that these two powers are essentially different, and distinct from one another. The opposite opinion, on the other hand, was maintained by Professors Steiglehner and Hubner, both of whom contended, that so close an analogy as that exhibited by these two classes of phenomena indicated the effects of a single agent. About the year 1777, the celebrated Beccaria engaged in a similar investigation, and although he, like his predecessors, failed in discovering the true nature of electro-magnetic influence, he observed that a needle through which an electric discharge had been sent, acquired a curious species of polarity, not turning north and south, but east and west. However, he did not follow up the train of inquiry indicated by this important fact. As philosophers had hitherto operated unsuccessfully with concentrated electricity, there were some who occupied themselves with this agent in a more tranquil form ; still, however, without success. Magnetic needles when charged with electricity were found to have the same influence on each other as when uncharged, hence it seemed that *quiescent* electricity, at least, was totally unconnected with the magnetic agent. The result of these experiments was, to diminish the belief in the identity of the two agents. True it is, argued philosophers, that violent discharges of electricity have generated magnetic properties, but their agency is most probably mechanical, and therefore, analogous to the effects of a smart blow, which, when applied to an iron bar in a particular direction—is known to develop magnetism.

When the disc- - ry was made of eliminating electricity by means of voltaic arrangements, philosophers were enabled to prosecute their electro-magnetic experiments under a new aspect, and then some advances were made towards a solution of the mystery. Ritter asserted, that a needle composed of silver and zinc, arranged itself in the magnetic meridian, and had been slightly attracted and repelled, by the pole of a magnet. He also stated, that, by placing a gold coin in the voltaic circuit, he had succeeded in giving it positive and negative electrical poles; and that the polarity so communicated was retained by the gold after it had been in contact with other metals, and appeared, therefore, to partake of the nature of magnetism. These experiments caused their author to entertain some vague idea that electrical combinations, when not exhibiting their electrical tension, were in a magnetic state; and that there existed a kind of electro-magnetic meridian, depending upon the electricity of the earth at right angles to the magnetic poles. Amidst much that is incorrect in the account just mentioned, it is yet evident that Ritter just discovered the first indications of true electro-magnetic influence; but in this state he left the subject, and so it remained until the discoveries of Professor Œrsted, in the year 1813. During his speculations on the subject, this philosopher was led to believe that, if galvanism were a form of electricity more latent than that from the machine, so magnetism might be nothing more than electricity in a still *more* latent form. I confess it is difficult to understand the tendency of this reasoning, but, at all events, it directed Œrsted to his brilliant discovery, of the mutual influence of electric currents, and magnets placed in the vicinity of each other. I do not know anything more difficult to describe than the direction of magnetic disturbance, under those conditions, although no experiments are so easily performed, nor, when performed, so easily remembered. A voltaic arrangement of one pair of four or five-inch plates is all the power required; and in order to prepare it for our electro-magnetic experiments, nothing more is necessary than to connect its two *virtual* extremities by a wire. This being done, we place a magnetic needle in various postures, with respect to this wire, and notice its various deflections. First, I place the magnet under the wire, and parallel to it; tell

north pole of the magnet being towards that end of the battery from which the electricity comes,—immediately you observe the north pole of this magnet turns to the right, until the whole magnet stands *pretty nearly* at right angles to the communicating wire. By altering the original position of the magnetic poles with relation to the current, a contrary result takes place, as also occurs when the magnet is held above, instead of below, the wire. If, instead of making the whole needle parallel to the conducting wire, only one pole be caused to approach them, it will be either attracted or repelled, according to the direction in which the current flows along, or to the pole which is approximated. It is difficult to view these experiments without imagining the conducting wire to be, so long as it transmits electricity, actually a magnet, and therefore necessarily affecting another magnet, according to the well known laws, that opposite magnetic poles are mutually attractive, and *vice versâ*. Now this, in reality, seems to be the case; for if I apply to the conducting wire, thus circumstanced, a few iron filings, the latter adhere. This fact, I believe, was first casually noticed by Sir H. Davy. In order to number easily the position in which a magnetic needle would be deflected by an electric current influencing it in any given direction, it is usual to avail ourselves of the following *memoria technica*, suggested first, I believe, by M. Ampère. Imagine that your own body transmits the influencing electric current: that the latter enters at your head, and proceeds towards your feet, and that, moreover, you hold in your hands in front of you a magnetic needle, with its north pole pointing to your head:—under these circumstances the magnet will arrange itself transversely to your body, with its north pole towards your right hand. The simple experiments just shown you, are in reality all that are actually requisite for illustrating the first principles of electro-magnetic agency. The motions which can be affected by means of this force are exceedingly complex and numerous, but they cannot be said to fall under the dominion of chemistry. It must be evident that, before a magnetic needle can be affected by a current of electricity, it must overcome its natural directive tendency. Hence, for delicate experiments, a magnetic needle used thus is usually rendered devoid of all or very *nearly* all directive tendency whatsoever, by mounting it on a pivot in association with another needle whose poles are in opposite directions to its own. Magnetic needles thus arranged, are termed *astatic*. If, instead of transmitting the electric current through one wire, many be employed,—or, what amounts to the same thing, if one wire be bent into several coils,—a magnetic needle freely suspended in the centre of such a coil will be deflected in proportion to the number of revolutions made by the wire. An instrument, such as this, is called a galvanometer—perhaps the term galvanoscope would be more appropriate. Within a certain limit (about 30 deg.) the angle of deflection is directly proportionate to the quantity of electricity which passes; beyond this, the connexion between the two follow a more complicated law, which does not fall within the province of any lecturer to demonstrate.

We next have to settle the question, if possible, why electric currents deflect a magnetic needle in the peculiar way first indicated? Nothing can seem more anomalous at first sight than the direction in which an electric current acts upon a magnetic needle; a direction which appears to be at right angles to the force applied; but more attentive observation leads us continually to suppose, that electricity, under many circumstances, traverses bodies in a helical direction, although it appears to go straight on. We are led, moreover, to believe, that all bodies thus traversed by electricity are magnets, and that the natural loadstone or magnet, so called from Magnesia, where it is found, has such currents of electricity naturally circulating in it. Every experiment which we can devise with the view of settling this question seems to do so in the affirmative. The first I shall point out to you is the following.—I take a helix of copper wire, and place within it a common sewing needle, folded in paper; now I pass several discharges of a Leyden jar through this helix, and on taking out the needle I find it does not attract either end of a magnetic needle indifferently; hence it must be *itself* a magnet.

If instead of machine electricity, I employ that emanating from a voltaic battery, and pass it through an insulated helical wire surrounding a piece of soft iron bent in the form of a horse-shoe, the latter becomes a magnet of most enormous power. It is remarkable that soft iron easily assumes this power, but loses it again immediately that communication is broken with the battery,—whereas steel, although assuming it more tardily, becomes an instrument of great permanency.

In order to bear out the theory of magnetism, which we have been just discussing, not only should magnetism be capable of development by electricity made to circulate in a helix, but by reversing completely the conditions, we should expect that electricity would be capable of development from a permanent magnet. Such, indeed, is the case, every time the armature of a horse-shoe magnet is approximated to it, or removed from it, a current of electricity is set up, and by using Saxton's magneto-electric machine, which consists of a strong horse-shoe magnet, before the poles of which an armature revolves with great rapidity, there may be developed electricity capable of generating all the most usual effects of this agent. You will see, then, that the term *magneto-electricity* is just the converse of *electro-magnetism*.

I will conclude this very interesting subject by drawing your attention to Ampère's beautiful theory of terrestrial magnetism. Why the magnetic needle pointed north and south, was a problem which philosophers long endeavoured to solve in vain. At present, we have at least a rational answer to this question. It has been demonstrated that heat will generate electricity, and it follows, from the known principles of electro-magnetism, that if a current of electricity is made to set up around our globe, at the equator, the earth must necessarily become magnetic in the direction of north and south, and must influence the direction of all other magnets on its surface, according to the usual law that opposite poles attract each other. Does then such an electric current exist? We believe there does, and that it is produced by the earth being heated in the direction of east to west, by the sun's rays. It has been determined, however, that there does not exist a single north magnetic pole, but that there are two, one in Siberia, and the other in North America—consequently, there must be two magnetic south poles as well, although their position has never been determined. These poles, or centres of force, are, however, not fixed; the needle continually changes its direction. At present it points to 24° west of north; but, in the year 1664, it pointed to the north—it previously pointed west, and is now returning to the same direction. Why there are two poles, or centres of force, in each hemisphere, we cannot determine; it is clear that only one should be produced by means of the thermo-electric effects of the sun, but many other sources of electricity, of which we know nothing, may exist: the directions of the secondary currents, thus produced, may be various, and the varying position of the magnetic poles may be nothing more than the changing resultants of two or more forces, not always possessing the same amount of intensity.

COURSE OF LECTURES ON THE THEORY AND PRACTICE OF MEDICINE.

Delivered by C. J. B. WILLIAMS, M.D., F.R.S., Pofessor of the Practice of Medicine, and of Clinical Medicine, at University College.

GENTLEMEN,—We see the effects produced by the existence of pus in the circulation in cases of what is termed suppurative phlebitis. The symptoms therein occurring are, great prostration, brown dry tongue, thirst, faintness, hiccough, delirium, quick feeble pulse, and an anxious expression of countenance, together with other indications of a typhoid state. When pus is thus absorbed, or otherwise conveyed into the circulation, it excites other parts to inflammation, having a tendency to suppurate, and hence deposits of pus are found in various organs of the body—these formations occurring as a result of previous suppuration, are called secondary or metastatic abscesses. It is stated, that pus globules are found not only in the blood, but that they have also been detected in the centre of coagula. Gulliver says decidedly, that it is disintegrated *fibrin* that exists in the centre of coagula, and certainly not true *pus*. Traces of lymph are frequently found deposited with purulent matter. There are many points connected with the origin of purulent formations that it is quite out of my province to enter upon, seeing that they belong to the chair of pathological anatomy. So long as pus can escape freely, little serious mischief may result; but it is, when it is confined and cannot get vent, that constitutional fever and irritation are produced: much will depend of course upon the situation in which matter forms, whether it is likely to be followed by serious consequences. Abscesses in the brain are, I believe, uniformly fatal. As a general rule, the more deeply seated an abscess is, the more dangerous it becomes. Even when pus is superficial, and can easily escape, yet, if its formation is extensive, it leads to great emaciation and hectic fever, which is characterised by flushed face, quick feeble pulse, partial heats occurring at intervals, alternated with chillness. The heat is felt chiefly in the soles of the feet and palms of the hands; because in these situations the cuticle is, as you know, remarkably thick, so that evaporation is prevented, and consequently the temperature continues high. The peculiar appearance of the face in hectic fever, constituting the hectic flush, at once indicates the nature of the affection to the experienced eye. The body becomes gradually wasted; the emaciation is sometimes extreme; there may also be much depression; patches of ulceration in the form of thin detached films frequently are present in the mouth, constituting aphthae; the urine contains a peculiar *pinkish* deposit. Towards the fatal termination of the disease, colliquative discharges very commonly supervene, such as vomiting, perspirations, and diarrhoea; these, as you may suppose, rapidly debilitate the patient, and soon bring his existence to a close. Hectic fever is said by some always to depend upon the presencence of *pus*; but, if this were the case, it would evidently be found only where pus was

discoverable,—and yet it is observed, in some diseases, such as diabetes mellitus, &c., where there is *no* pus. Although there is no pus, there may be some other *poison* in the system to cause the symptoms. It is in the young and irritable that hectic is principally noticed. Although pus is undoubtedly noxious in its effects, it is not so bad as gangrene. It seems to have a great tendency to run into putridity, and give rise to the disengagement of sulphuretted hydrogen; still there are instances of pus remaining in a good condition for a very considerable length of time when excluded from the air. Rigors occurring during inflammation, are pretty conclusive of suppuration taking place, except in diseases of the urinary organs. In diffused suppuration rigors, too, are often absent. Suppuration is frequently beneficial, especially in mucous membranes, as in cases of bronchitis—it tends to remove the thickening—but even from a mucous surface the discharge of pus will, if long continued give rise to hectic symptoms. We have now passed in review as results of inflammation, the occurrence of effusion, softening, adhesion, induration, ulceration, and suppuration, and the last I have to mention is *gangrene*. The symptoms of this termination will depend, to a very great extent, upon the strength of the constitution and the vascular process—if the subject is strong, the irritative fever may continue high, and no depression occur: the vascular action defends the system from the influence of the poison and keeps up the fever. But generally there is depression present, and relief from pain on the supervention of gangrene; the tongue becomes brown and dry; the breath putrid; pulse feeble; countenance collapsed, and features tremulous: cold fetid sweats and low delirium, with hiccough, occur, and death speedily follows. Externally, there is a characteristic putrid odour. It is recognized in the intestines by the fœtor of the alvine excretions. In phthisis, there is often a very fetid odour communicated by the breath and expectoration; it may also arise in bronchitis. The gangrenous smell is very much like that of the dissecting-room. It is especially liable to occur in dilated bronchi, because the matter becomes lodged in them, and is there decomposed. A very fetid odour often arises from lymph decomposing on the fauces. Thus we see that very putrid odours may arise from decomposition of secretions, and does not necessarily indicate any actual sloughing of the tissues. There is no very absolute line of demarcation between pus and gangrene. We saw that lymph and pus may be mixed, forming purulent lymph, so as not to be clearly distinguishable from each other; and so, too, may gangrene and pus be mixed. Pus may be almost gangrenous. A gangrenous abscess presents a most lamentable condition.

We have now to consider a few of the principal *divisions* of inflammation. The chief of these is the *sthenic*, in which the power of the heart and vessels is active and remarkable; it is also characterized by an inflammatory condition of the blood itself, as indicated by its containing a large quantity of *fibrin*. The tension of the arteries is great, and the fever high. This sthenic form is also acute. In the *asthenic* form, the inflammation is not backed by much vascular activity; and the blood is not nearly so rich and fibrinous. A variety of inflammation is described, by Cullen, as *phlegmonous*; but this is not a distinct species. It is seen in cellular and compound textures, where it is circumscribed by effusion of lymph, and may tend to suppuration. The inflammation is not diffused, but this fact depends rather upon the tissue than upon any thing specific in the nature of the inflammation itself. The inflammatory fever itself is generally high. Another kind of inflammation, and one that appears to be just the opposite of the former one, is the erythematic, or erysipelatous, which is specific in its tendency to *spread* in all textures. It leads to the effusion of serum, with *little* lymph, so that circumscription is not effected. The effusion takes place frequently under the cuticle, forming vesications and œdema. The fever that accompanies this inflammation is often of the typhoid type, and not uncommonly precedes the inflammation. In addition to the prostration, delirium, dry tongue, &c., there is unusual disorder in the *secretions*. The symptoms appear to be out of proportion to the amount of inflammatory action, so that we must conclude there is something specific in the constitutional state. Erysipelatous inflammation has a tendency to attack the peritoneum in puerperal fever; women are specially liable to puerperal fever at the time that erysipelas is prevalent. The larynx is particularly subject to erysipelas. This inflammation often follows external injuries. It frequently prevails epidemically, and may, unquestionably, be propagated by contagion,—it is, in fact, a *poison*. It is apt to occur chiefly in bad situations, and attacks most commonly the surface. It may attack mucous membranes, as in the fauces, &c. It sometimes affects the pericranium, and sometimes serous membranes. The effusion produced by this kind of inflammation is more liquid than usual; the lymph is curdy and shreddy. There is sometimes a film secreted over the ulcerations, which decomposes readily, and exhales a fetid odour. This form of inflammation is called *diptheritic*.

Another species of inflammation is the *rheumatic* and gouty. This is derived from the condition of the blood. It does *not* tend to *suppuration*, but to the effusion of serum into the joints. In the pericardium, lymph is effused. The blood is very buffy, the urine scanty and high-coloured, and the perspiration *acid*. It generally occurs in habits previously diseased, and is remarkable for its tendency to move or shift about from one part to another. It chiefly affects *fibrous* tissues, as tendons, fasciæ, the pericardium, dura mater, &c. It depends upon some materies morbi in the system, or, as is generally admitted, upon *lactic acid* in excess. *Gouty* inflammation attacks more particularly the *smaller* joints. It is almost invariably associated with a deranged condition of the stomach, and very frequently with gravel in the urine. If the disease exists long, there is a peculiar deposit noticed in the joints consisting of lithic acid and soda. It is most common in plethoric subjects. Another variety of inflammation is the syphilitic, which depends clearly upon the presence of a specific poison in the blood; it attacks various parts of the body, especially the skin, periosteum, the bones, the eye, and the lymphatic glands. In the skin it tends to suppuration—in the periosteum to exostosis—in the iris to the effusion of lymph—in the mucous membrane of the eye and urethra pus is formed. The last species of inflammation that we shall notice is a very important one, viz., the *scrofulous*. Its effects are chiefly manifested in the lymphatic glands. In ordinary inflammation there is much heat and pain experienced, but in scrofulous cases the pain is generally slight and also the heat —the redness is rather lurid. There is a remarkably slow tendency to termination, so that the disease is very tedious; it leads to hypertrophy of the glands. The pus that results in scrofula, or in other words "scrofulous pus," has a peculiar *curdy* or *cheesy* character that is readily distinguished; it is more *serous* than ordinary pus. The abscesses that arise have little disposition to heal, and are prone to insinuate into the cellular tissue. Another peculiarity of this inflammation is that the usual antiphlogistic remedies are productive of little or no benefit. There are several signs by which the scrofulous diathesis is easily recognised, such as general relaxation of the solids—transparent skin appearing soft and fine, and shewing the veins very distinctly under it—the countenance is pale with circumscribed livid patches—the eyes have a *pearly* aspect—the hair is generally fair, frequently reddish—the upper lip is remarkably tumid—the glands have a special liability to enlargement. In scrofulous subjects, moreover, there is often precocity of intellect, wounds are caused to heal with difficulty, the joints frequently become swollen, the skin is dry and hard, or else it is soft and clammy. The synovial membranes of joints are very subject to disease, also the cartilages, especially ulceration of the nasal cartilages, also tuberculous disease in all its forms. It is quite evident that scrofula is a disease of the *nutritive* secretion. The causes of scrofula are debilitating influences long continued. It is undoubtedly hereditary. The children of old or gouty and dyspeptic parents are specially subject to scrofula. It may be excited by poor food, cold and wet, confinement in impure air. It is exhibited most commonly in winter and spring, particularly after fevers and long illnesses. Patients who suffer from it, experience relief and improvement during the summer months. Scrofula gives a tendency to chronic inflammations. It does not exist in the same form in warm climates as in cold—in the hot climates the *liver* is the chief sufferer. The predisposition is exhibited in people coming from hot climates to cold. It much modifies *acute* inflammations and lowers the vitality of the products of inflammation, for if lymph is effused, it is not organised at all, or else only in a low degree; it is not assimilated to the tissue in which it is secreted, but gives rise to chronic induration tending to ulceration; it may be quite *aplastic* forming empyema. The matter of scrofulous abscess differs from ordinary pus; the globules of the former are granular, and not vesicular, as those of pus. Scrofula depends upon some diseased condition of the blood, or of the assimilative functions.

CYNANCHE MALIGNA.

BY A COUNTRY PRACTITIONER.

Inflammation of the tongue, the uvula, and soft palate, the fauces or tonsils, when of the ordinary kind, or what is called *common inflammation*, although attended by local symptoms sometimes of a very distressing character,—pain in swallowing, feeling of fullness in the throat, accompanied with choaking sensations and laboured respiration, at the same time, considerable febrile disturbance, frequent and full pulse, furred tongue, headache, &c.,—is not, generally speaking, to be regarded as an alarming or dangerous complaint. The object of this paper, however, is to contrast the above forms of disease with other maladies attacking the same parts, different in their nature, and more to be feared as to their results; although at their commencement, they have occasionally characteristics so much in common with the affections of the first class, that the young or incautious practitioner is occasionally betrayed by a deceptive similarity, if not into the adoption of an erroneous treatment, at least into the giving to friends of that which turns out to be an unguarded or incorrect opinion. In towns, where the population stands thick on the ground, and where medical practitioners at any given time have every facility of knowing whether or no epidemics exist in the neighbourhood, it is not only comparatively easy to know of their existence, but also to make ourselves more or less acquainted with their nature; but in country places, where the inhabitants are thinly strewed, small in number, over a great extent of surface, the medical attendant cannot generally be so well informed respecting the extent or nature of epidemic forms of disease which may now and then prevail,—so that on his first being called to an isolated case, or one which, in the commencement, appears so, from the fact of its being the first he observes of that which afterwards becomes a series—a complaint which might justly be called malignant—is regarded as the commencement of a benign and curable affection; whence some occasional mistakes we make in prognoses, which although they may have had little to do with modifications of treatment, are all important as regards the expectations, confidence, and opinions of friends. It is especially with a view to throat affections, and to the differences between the common and curable, and the specific, epidemic, or contagious, that the following remarks are put together, without any attempt at method, merely for the sake of the practical utility which they may probably be allowed to possess.

Although the term malignant sore throat is so commonly employed by English practitioners, its propriety has been called in question; in like manner another term often used by French writers, to qualify the same kind of disease, viz. *asthenique*, has been regarded by some recent writers on the subject, as essentially incorrect, inasmuch as it is said to be contrary to reason and sound physiology, that the same inflammation, that the same peculiar formation of false membrane, such as in these cases,

lines the throat affected, should in one case be the result of weakness and in another of strength, on the one hand associated with an exaltation of vital energy, on the other connected with its depression. The term *sthenique*, being the opposite, employed in speaking of that form of the malady distinguished more by symptoms of common inflammatory action; perhaps of the terms *malignant* and *asthenique*, the former is the better of the two, by virtue of its more popular and less scientific character; it commits the practitioner to no peculiar opinion, as he is not often asked the difference between the malignant and the benign. Many diseases are known to affect very differently different constitutions; and it appears to me that the progress, duration, and termination of throat affections, are influenced as much by peculiarities of individual constitution, as they are by peculiarities of disease, or morbid action, yet as there is a difference between the synocha of Cullen, and the typhus gravior of the same author, so certainly is there a difference between the attack, progress, and symptoms, of common sore throat, inflammation of the tonsils, palate, &c., and those of cynanche maligna, which has the same anatomical locality: for in the former case we have to combat an active inflammation, by active antiphlogistic means, attempting to procure termination by resolution, opening abscess early if it occur; in the latter, where one characteristic of the symptoms is what might fairly be called typhoid, (if here we might be allowed to except the stupor) the tonic and antiseptic treatment must never be lost sight of, while to abstract blood, in many cases, might even prove fatal, and the practising of counter-irritation in the immediate neighbourhood of the parts affected, is not always unattended with danger.

In one fatal case which came recently under my notice, in a young lady, aged eleven, the throat affection was at first of so simple a character, that it was regarded as a case of ordinary quinsy, and during the first four days of its progress, no symptoms appeared, sufficient to make the practitioner from the first in attendance, in the least apprehensive with regard to the results. After this period, the change in the general aspect, and in the breathing, was so obvious that the friends became anxious for the safety of the child, for by this time the false membrane lining the fauces, and thickly covering the tonsils, had all the appearances that characterize the worst cases of cynanche maligna; the breath became exceedingly fœtid, the pulse very frequent and small, the respiration gradually more and more oppressed, till the fatal termination took place on the fifth day of the attack. In this instance it would seem, from all we could learn of the nature of the early symptoms and progress, there must have been some difficulty at the onset in establishing a correct diagnosis, and this more especially before the peculiar coating given by the disease to the tonsils and neighbouring parts, had been carefully observed; for after the ash coloured and spotted aspect of the throat, so characteristic of cynanche maligna, was observed, and this, in connection with the peculiar fœtid breath, the frequent and very small pulse, and the general prostration of strength, the complaint could no longer be regarded as ordinary quinsy, nor could it be supposed capable of relief by the treatment which suffices in common inflammation of the tonsils and palate. M. Dupuytren directed his attention some time ago to the treatment of the severe forms of cynanche maligna, and has recommended the employment of the "chloro-sodaic solution" of Labarraque in gargles, a practice also adopted by Guersent, Roche, and Sanson, who have reported favourably of its effects. To such treatment, in adults, the inhalation of oxygen gas might be added, and where the sitting up to inhale this gas is attended with difficulty, or where we are not furnished with the necessary apparatus, we may substitute the following method, recommended by Thomas: "Cause the windows and doors of the patient's apartment to be closed, and then, taking a chaffing dish with some live coals, throw into it half an ounce of purified nitre in powder, which will fill the room with a thick white cloud that will continue for a considerable time. This process ought frequently to be repeated in the course of the day." We are recommended by some practitioners to take great care in preventing any part of the secretion or false membrane formed on the fauces from passing down the œsophagus into the stomach; and this precaution appears more especially necessary in children of feeble constitution, for the gastric irritation which might thus be set up, would be in such cases a grave addition to an already serious complaint. When the matter in question is loose enough to be removed; this may be done by a little fine soft sponge, tied to the end of the strong handle of a camel's hair pencil, or to the end of a common black-lead pencil, at the other end of which may be attached another portion of sponge, with which any stimulant or other application may be carried to the denuded surface of the throat, and its healing in this way favoured; the patient at the same time, if sufficiently old and intelligent, being recommended to make occasional efforts to expel loose shreds of this formation by the mouth. If we have reason to think that any disturbance of the bowels,—griping, purging, &c., which may occur, is caused in the manner now alluded to, we had better not employ astringents to stop it, but instead, an occasional small dose of castor oil, to which, for the sake of allaying irritation, a few drops of laudanum may be added. At the commencement of the attack, having attended to the state of the bowels, we find that some degree of benefit generally follows the action of sudorifics, which, however, in most cases, are only admissible in the early stages of the complaint, for a treatment by diffusible stimuli is often indicated, within the course of the first three or four days, when mixtures containing ammonia or æther, more or less, according to circumstances, will come to our aid in such cases as are distinguished by the aspect of great debility. In short, this view may be safely taken of the malady as it affects different constitutions, that in some there being sufficient strength to begin with, reaction on the system takes place, the pulse becomes moderately full, and the skin warm, with occasionally more or less head-ache, symptoms of inflammatory fever prevailing; in others, instead of this reaction, which declares itself chiefly in the state of the heart and circulating system, of which the pulse is taken as a principal index, the powers of the system are overcome by the energy of the disease, and reaction does not take place, but gradually an aspect of debility supervenes, the pulse is frequent and small, the patient lies prostrated by the complaint, and it is with pain and difficulty that the ordinary efforts are made for the employment of remedies, a state which is sometimes called typhoid here taking the place of that which has been designated inflammatory fever in the other instance; now the difficulty is to distinguish well between these conditions, and to establish such distinction at the earliest possible period, inasmuch as the treatment must be influenced more or less by the balance of indications, which will differ considerably, as far as the remedies to be employed are concerned, as they belong to one or the other of the states, to which we now allude. It is to be recollected that the former set of symptoms are generally favorable, and that the latter are the opposite, so that great care should be taken that we do not by any part of the treatment, favour at all the occurrence of the latter condition, for this may easily be done, and it has occasionally happened that during the prevalence of the first state, blood in too great a quantity has been incautiously abstracted, when unexpected debility and the so-called typhoid state have followed, so that if by leeches in considerable number, or by other modes of letting blood from the throat, we reduce the patient too much, the chances of recovery, which might otherwise have been afforded by the strength which he possessed at the beginning, will be reduced in the same ratio as the powers of the constitution, and we shall have to regret the loss of a sheet anchor, which no art can restore or bring back. In cases, therefore, of cynanche maligna, or in any milder form of throat affection likely to end in it, the practitioner will have to watch diligently at the bed-side of the patient if he wish to mark the distinctions we have noticed, or to vary his treatment in accordance with the progress of the case.

A French author speaking of the morbid appearances found on dissection in these cases, remarks, that no traces of gangrene are to be met with, only the vestiges of inflammation, and that nothing but an erroneous notion has led to the adoption for this complaint, of the term of "*angine gangreneuse.*" We cannot, however, understand this objection to the term gangrenous as applied to many cases of this disease, for not only do we meet with vestiges of grangrene after death, but even during life the progress of the gangrene is in many instances only too apparent. We have seen several cases where gangrene commencing in the throat, has made rapid progress from the mucous membrane towards the skin, destroying most of the intervening structures along with the mucous and tegumentary tunic; the ravages of this severe form of the complaint are generally such as to destroy life, soon after the gangrene has reached the exterior and the throat has been laid open; to this, however, we meet with interesting exceptions.

A case came under our notice some time ago, where, by the process of gangrene, the carotid sheath was exposed, and the nerves of the neck, as it were, beautifully dissected by the sloughing of the surrounding textures; this case for some days after the separation of the sloughs appeared to be doing well, healthy granulations arising from the exposed surfaces; the child, however, was irritable and exceedingly cross, and the mother, not being a good manager, allowed the patient one day to get into a sort of juvenile rage, and during this a small artery in the neck began to bleed, by which the sufferer was so much reduced as to sink from the effects of the hæmorrhage.

We have frequently had opportunities of observing, that in bad cases of cynanche maligna blood-letting is decidedly useless, at the least, if not practised at the very onset of the complaint, and here it should be local—as by leeches behind the ears, or cupping at the back of the neck, and not general, for in this there is often risk of doing harm, as before mentioned. We do better to avoid the application of leeches or blisters to the throat, or in the immediate vicinity of the parts affected; for cases are now and then met with which seem to have escaped from the injury inflicted by the disease in the fauces, but which fall a prey to external gangrene following the application of a blister to the throat itself. On account of the disposition to slough, which the blistered surface not unfrequently takes on, even where more serious consequences do not follow, the blisters on the throat should be avoided, for the scar afterwards left, presents, in many instances, a very hideous aspect, more especially to be dreaded in females.

It appears to be questionable, and matter worthy of consideration, whether in cases of cynanche maligna, where no affection of the skin generally has been observed, it might not be good practice to employ the cold affusion, which has been so much recommended in scarlet fever, where there is great heat of surface, and from which no doubt fever patients often experience very great relief. This might rouse the capillary circulation into vigorous reaction, and if at the same time sinapisms were applied to the feet, to the legs, and even to the thighs, some derivative effect might be hoped for, more or less likely to relieve the throat and neighbouring parts. With regard to the local treatment at the commencement, I should have no hesitation in applying with a small brush a good strong solution of lunar caustic to the tonsils and neighbouring mucous membrane on either side, with a view of altering the action of the part so much as to give a chance of getting rid of the complaint by resolution; and as I am convinced, from the observation of a considerable number of cases, that in some respects the complaint before us is analagous to carbuncle under the external tunic of the body, I should be disposed to bear in mind always the practice we resort to in many cases of carbuncle,—viz., that of making a way to the exterior for dead portions of cellular membrane, by the crucial incision, &c.—aware all the while of the necessity of guarding against unnecessary loss of blood in every instance of cynanche maligna. This comparison may appear somewhat strange; carbuncle might be said

to occur on any part of the body, cynanche maligna only in connection with that part of the mucous membrane which lines the throat. We may recollect, however, that the œsophagus, as well as other lower parts of the intestinal tube, is occasionally affected in cynanche maligna, shewing that there is at least a tendency to morbid action throughout the extent of the mucous membrane, for indeed the bronchia do not always escape intact.

What carbuncle is then to the skin and cellular membrane beneath it, such is the tumour in cynanche maligna to the mucous membrane and subjacent cellular structure; for the complaint is not especially connected with the tonsils in the same degree that ordinary quinsy is, nor could it with propriety be styled, malignant tonsillitis. There are certain differences, no doubt, as regards the state of body under which the two diseases make their attack, besides which we meet with cynanche maligna, as an epidemic—I would rather say an endemic; even in this, however, there are certain points of resemblance chiefly to be sought for, as far as carbuncle is concerned, in the history of diseases of some parts of Asia and other warm climate. There is in many cases, more especially at the onset, a certain resemblance between the affection of the mucous membrane in cynanche maligna, and that of the skin in erysipelas; we will not, however, carry this paper beyond reasonable bounds by constituting further comparisons.

Most of the cases alluded to in this paper were unconnected with any cutaneous eruption, not cases of scarlet fever with severe affection of the throat, but malignant sore throat alone; the case of the young lady, which terminated fatally, being one of a somewhat numerous group where the disease attacked almost every member of a large family residing in the country, without any known cause, or our being able to trace its approach from the spread of any neighbouring epidemic.

GALL AND DR. MACARTNEY.

To the Editor of the 'Medical Times.'

Sir,—Dr. Macartney in the Transactions of the Royal Irish Academy, quoted in your last week's paper, page 151, column I, says:—"If we can ever arrive at correct notions of the functions of the brain, it must be by careful dissections of the interior parts of the cerebral organ, and by ascertaining the correspondence between the minute structure, and the endowments and dispositions of the different individuals; taking into account at the same time, the influence of the various organs of the body, *instead of ascribing to certain parts on the surface of the brain, distinct and often opposing faculties as Gall and Spürzheim have done.*" Without stopping to consider the practicability of the method proposed in the first half of this sentence, (which method is about as excellent as wandering over the ocean would be without a compass), I wish to direct attention to the words in italics, which are intended to insinuate a refutation of Gall's doctrines, or at any rate to charge them with gross absurdity and inconsequentiality. As many who read this sentence may take Dr. Macartney's dictum as sufficient without examination, I take the liberty of subjoining what Gall himself really taught respecting "certain parts on the surface of the brain." Gall: Sur les Fonctions du Cerveau, tom. iii., p. 2, 8vo. ed. "Is there a relation or determinate correspondence between the brain, the cranium, and the head? The possibility of resolving this question, supposes that *the organs of the mind are situated at the surface of the brain*, that they are more or less depressed, more or less flattened, more or less elevated, more or less small, according as the exercise of their functions is susceptible of a greater or less degree of energy; that these varieties in the form of the individual parts of the brain are shewn on the surface of the cranium and head; *assertions which must be rigorously proved.* . . . The following observations will serve to answer the question,—*how far is it true* that the organs of the mind are situated on the surface of the brain? We must recollect that every nerve, after having been sufficiently strengthened, ramifies and spreads in the part where it has to exercise its function. The nerves of sensation and of motion spread in the skin and muscles; the nerves of sense, each in the exterior apparatus peculiar to itself; e. g., the olfactory nerve in the pituitary membrane, the gustatory in the tongue; the optic, by its expansion, forms the retina. *This part in which the nerve spreads is not, it is true, all the organ; but we may infer the magnitude of the nerve itself from the extent of its expansion.* The expansion of the olfactory nerve in the dog and the horse is more considerable than in man; and the nerve itself is larger from its origin to its expansion, in these animals than it is in man. *Nature follows precisely the same law in the brain.* The different parts of the brain arise and are strengthened in different places: they form fibrous bundles more or less considerable and finally spread. All these expansions of different bundles, when united, form the hemispheres of the brain. These hemispheres are then nothing but a nervous membrane, two or three lines in thickness, completely covered externally by an apparently pulpous or gelatinous matter of a greyish colour. Imagine this great nervous membrane (as it may be seen in some hydrocephali), folded like a flounce, so that each fold is from 12 to 16 lines (more or less) in depth? convolutions will arise, the intervals between which have received from anatomists the name of anfractuosities; and we shall have the two hemispheres, such as nature has deposited them in the cranium in their folded state. The expansion of the olfactory nerve forms analogous folds in the buttons of the nose. A small bundle or fascia can only form a small expansion, and consequently small folds, and a small, or several small, convolutions. On the contrary, a nervous fascia of considerable size, forms a very wide and thick expansion, and consequently very much more voluminous folds and convolutions. Hence *although all the portions of any cerebral organ are* NOT *situated at the surface of the brain*, from their origin to their expansion, *we may nevertheless from the magnitude of the fold or convolution, conclude with certainty concerning the volume of the whole organ.* The wider, longer, and deeper are the convolutions, the more space they occupy, and the higher they rise above those which are not so long, deep, and wide: so that a brain, the integral parts of which have acquired an unequal development, offers at its surface hollows, flat parts, and protuberances." It is needless to pursue the enquiry further. Enough has been said to shew that Gall did *not* teach that the organs *themselves* were situated at the surface of the brain, but that we can, by their expansions there situate, conclude concerning their whole volume, which is very different. As to the sneer implied in the words "opposing faculties," it may be left unanswered, as Gall may be allowed to suppose he has proved the existence of faculties which in their exalted state are widely different, until the metaphysicians have proved, not only *a priori* that such faculties *cannot*, but *à posteriori* that they *do not* exist. As the notion that the organs are only situated on the surface of the brain, according to phrenologists, is a very common error, I have ventured to intrude thus much upon your columns, in order to shew that Gall never taught such a doctrine. I am, Sir, your obedient servant,

A. J. Ellis.

Dorking, 7th Dec. 1842.

THE NEW MEDICAL REFORM BILL.

(To the Editor of the 'Medical Times.')

Sir—The draught of Sir J. Graham's bill for reforming British Medical Government has been recently placed in my hands, and I do myself the pleasure of asking leave to communicate its contents through a journal which, however remarkable for the energetic ability with which it exposes abuses, is not, at least to my humble perception, less distinguished for the spirit of honest candour with which it can regard both the character and measures of gentlemen with whom, in general, it shews no concurrence of sentiments. Practically, I am sure your object and mine is the same—the usefulness, the happiness, of our common profession; and I am sure that whatever less liberal, because less enlightened, critics may do, you will neither pronounce me, *ex cathedra*, as imbecile of mind, or wanting in sincerity, when I assure you that, taking every thing into account, I consider Sir James Graham's bill the very best which we can hope for under the circumstances—and which, if it fail to shew the speculative perfections some sanguine politicians ask for, will produce all the practical good which the profession is really desirous of, or prepared for. It is all very well to talk of representative systems, and Faculties, but where are your men to enact them?—and where, if you get them enacted, are your men to work them? What are your associations? One of them, the British, is, or ought to be, dead,—if not defunct, its existence, after your narrative of its *decent* orgies and *respectable* organization, must prove an indifference to personal character, in its members, as well as leaders, which must make it something worse than useless to the projects which they are supposed to support. The other, the Provincial Medical and Surgical Association, is a "*res non.*" A periodical which once enjoyed great notoriety, and whose recent extinction is a proof how little its violent medical politics met with sympathy from the profession,* some time since pronounced it an utter failure, and I have my doubts whether the Association has any creed of medical reform which they dare to promulgate, or ask subscription to. You yourself are constantly complaining of the apathy of the profession, which, with due deference to you, is but another word for expressing its dislike to all excessive changes,—so that, Sir, externally, and internally, in the measures proposed—in the authority in their favour—in the disfavour, discredit, and powerlessness of the agitators—in the tacit opposition of the profession to all their schemes of violent disrupturing of our medical polity, I see reasons for supporting the moderate measure of Sir James Graham, which, without making a revolution which would do thousands harm, effects all the substantial practical reform which can do any well-meaning and honest man good. I am aware that my sentiments do not accord with yours, and not to increase the risk of their omission in your publication by further prolixity, I proceed to lay before you the details of a bill which, I think, has the highest claims on my fellow-practitioners' approval.

First—the constitution and government of the two Colleges of Surgeons and Physicians are to be practically assimilated.† — Medicine, Midwifery, Pharmacy, and Chemistry, on the one hand—and Surgery and Anatomy on the other, are to form distinct subjects of examination. The first will be supervised by the College of Physicians, the Apothecaries assisting them: the second, by the College of Surgeons—a most wise regulation. This double examination will give a title to practice as General Practitioners. After increased study or practice, these may take the higher degrees of Doctors of Medicine or Surgery, or both, after renewed examination of a still stricter character. Each and all of these examinations may be presided over, at pleasure, by any member of the Central Council of Health—a Board formed of one of the two Secretaries of State, four non-professional members, nominated in perpetuity by the Government, and eight physicians or surgeons, representing the English, Scotch, and Irish Colleges—four for England, two for Ireland, and two for Scotland, selected by Glasgow and Edinburgh alternately. Government appoints unreservedly the whole Council in the first case, and subsequently chooses two for each Colleges, from lists of fives, furnished by the Colleges respectively. And, Sir, whatever your opinion may be on the necessity of medical men for their own government, a little reflection will teach that a few lay-

* Our correspondent (as if influenced by coming events, which, we are told, cast their shadows before) evidently labours under the mistake that the *Lancet* is already given up. This is not *yet* the case. Journals, like some other sufferers, will sometimes linger on a long time in *articulo mortis*.—Ed.

† We have omitted a portion of our correspondent's remarks here, as all this was detailed in a former Number.

men are not without use in their deliberations. If medicine do not, like law. narrow the mind, it contracts the heart—and we never behave better to each other, and our profession's repute, than when under the public's eye. The way to have us harmonious, and not personal, is not to leave us quite to ourselves. The mode of retirement is wisely arranged. After the first eight's withdrawal, the professional part of the Council will be re-composed every four or six years—the precise period, I am told, not being yet fixed. Though it was designed, originally, that the President (the Secretary of State) should nominate the vice-president, who was not to be a medical man (an equivocal proceeding, I own)—I am told that a change is here in contemplation, two of the Colleges having made strong objections to this plan. Another wise provision is, the great power which this Central Council will exercise over every rule and bye-law of all the Colleges. It will cause a perfect unity in the medical community—build them, if, Sir, I may so express it, into one large house, with a pleasing variety of apartments—and give us general rules, by which our qualifications and respectability will be made matters of assurance to the public.†

In conclusion, Sir, as an old man of some experience, I would recommend you, and the profession with you, to examine this bill as you ought to do, and not squall because you have made a custom of it—nor go on asking if, in the book of platonics, something nicer might not be fashioned—but whether, with due respect to existing interests, and practical legislating in the homely business way which suits Englishmen, anything could be produced so likely to obtain the sanction of Members of Parliament—many of whose sentiments I have the honour to know personally—and, at the same time, satisfy the reasonable part of our brethren. Some men, I know, nothing will satisfy in the way of medical improvement, except it would teach them to keep the bailiff out of their house, or entrap patients in, —but you, Sir, and such as you—excuse my frankness—know better, and should do better.

MILES NON SINE GLORIA.

N. (?) 29. 1842.

[Our frank-spoken correspondent has our warm thanks for his communication: though, we confess, his logic, practical as he considers it, is not of the sort to make us converts to his opinions. No doubt, with him, we only seek the *practical* well-being of our profession; and if that be *secured*, *guaranteed*, we shall not care if in Acts of Parliament, there existed no word about us—or if there did, that in them, and *on paper*, we were the most incongruously-arranged polity in the State. But our objection to the new bill (not repeated from a *habit* of opposing governing bodies, as our correspondent insinuates) is that it will fail either to produce, or producing, fail to *secure* that practical well-being which forms, we freely own, the only reasonable object of all legislation. The education of medical men is left too much at *discretion*—rewards and encouragements to scientific merit are far, very far, too much overlooked, and protection to the practitioner, and, through him, to society, is too little recognized in Sir James Graham's bill, ever to permit us to support it in its present form, on our correspondent's ground that, though deficient in theoretical excellence, it abounds in practical perfections. This is a subject, however, to which we shall shortly have again to direct our readers' attention.—ED.]

CHINESE PROGRESS.—We have heard it stated, on authority on which we can rely, that a surgeon to one of the principal London hospitals has been applied to, to receive a young Chinese into his home, to teach him the art and mystery of surgery.—*Globe*.

† Our correspondent gives us, here, some further details as to the registration of medical men, and their legal separation from quacks, which, as published in the Number before referred to, we have taken the liberty of omitting.

WESTMINSTER HOSPITAL PHYSICIANSHIP.

(To the Editor of the 'Medical Times.')

SIR,—In the last number of the *Medical Times*, my name is introduced as one of the candidates for the Physicianship of the Westminster Hospital, about to be vacant by the retirement of Dr. Burne. I beg, however, to state that I am no longer a candidate for that situation. The Committee of Management of the Westminster Hospital had previously to my appearing on the field, unanimously resolved, I found, to recommend to the Governors my able colleague Dr. Basham. In thus resolving to support Dr. Basham, I am perfectly satisfied that the committee have acted from the purest motives, and have had a regard solely to the well-being of the hospital over which they preside, and have besides adopted the only legitimate course in their power of counteracting the nefarious practices which you have so strongly condemned, and which at present threaten to destroy the independence of the committee, as well as the good name and usefulness of an excellent hospital. Under these circumstances I have deemed it proper to retire, to leave the committee unshackled in carrying out their good work, and hope to be able at some future period to appear before the Governors of the hospital under more propitious circumstances.

I am, Sir,

Your obedient Servant,

ROBERT HUNTER.

Westminster Hospital School of Medicine,
Dec. 6, 1842.

To the Editor of the 'Medical Times.'

SIR,—I am an old subscriber to your valuable paper. I am also an old subscriber to the Westminster Hospital, and am one of the Managing House Committee. Under these circumstances, I take the liberty to trespass on you with a few words, in regard to the forthcoming election of physician to that charity, induced by the very able, humane, and proper remarks contained in your last week's number, as well as to set you right in regard to the general feeling of the House Committee respecting this disgraceful job. You may not be aware that the Committee has been kept most studiously in the dark as to the expected resignation by those concerned in the intrigue, and when about three weeks since, a sum exceeding three hundred pounds was reported to have been paid by new governors, all were at a loss to know from what source. "These soft impulses of divine benevolence" so suddenly arising in favour of this "distracted" charity, it was conjectured that some surgical move was on the *tapis*, and one of the surgeons who has an expectant son, forthwith found thirty more charitably disposed persons to add to the amount, in his favour of course, but in a short week it comes out that one of the physicians is about to retire from practice, and has given his sanction to a private and active canvass in favour of Dr. Kingston; it is reported, in consequence of pecuniary negotiations regarding a house and furniture, &c. &c. Alas, poor hospital, how art thou sold? Will not this transaction confer a most honourable distinction on the gentleman who retires from a public appointment into private life? After having so sedulously and scientifically discharged his hospital duties for so long a period, and to leave the institution bordered with a pitiful job for the committee to contend with.—which I assure you, they are most anxious to destroy if possible, as they are about to pass a resolution, "That the next election of physician shall be for one year only." It will then be seen whether the new governors will continue to support the hospital and their present candidates. I fear your proposition to defer the election *sine die*, and appoint a substitute in the interim, cannot be adopted as the rules regarding vacancies are imperative. Allow me to subscribe myself a well-wisher to the hospital, and your much obliged subscriber,

H.—M.R.C.S.

Pimlico, Dec. 6, 1842.

[We have learned from other quarters, besides the letter of our respected correspondent Dr. Hunter, and our friend "H.," inserted above, that the "*House Committee*" of the Westminster Hospital are exerting themselves to rescue the hospital from the foul disgrace which the dashing policy —the storming tactics of our young Hospital Alexander are calculated to inflict. The meeting of the committee on Wednesday last was more than usually interesting. The conduct of Dr. Burne regarding the alleged *arrangement* with Dr. Kingston, and the subsequent swamping the affairs of the hospital by an inundation of "*pocket voters*," was animadverted upon by Mr. Bicknell in strong and indignant language, and the dangerous consequences to the hospital forcibly pointed out in almost the *ipsissima verba*, in which we denounced the transaction in our last number. In the midst of the discussion, Dr. Burne himself appeared, and being called upon for an explanation, spoke on every thing but the subject in question. He offered, he said, to sell his house to Dr. Kingston for less than it was worth, and ultimately sold it to another person altogether. He had no time to refer to the furniture he sold Dr. Kingston, regarding which many curious rumours are afloat. The doctor spoke long, and said nothing, and when questions thick as arrows, were thrown from all parts of the committee-room at his devoted head, he grumbled out something about not submitting to cross-examination, and with an agility quite astonishing, bolted out of the committee-room. Dr. Kingston, the protegé of Dr. Burne, was not, however, so easily abashed. He boldly defended the principle of "pocket voters"—maintained that others had acted as he had done, and that the introduction of two or three hundred Governors of his own making, to force him over the heads of more worthy candidates, was perfectly constitutional, and calculated to add to the funds, if not the fame of the hospital. All this logic was lost, however, upon the committee, for they immediately, by an overwhelming majority, resolved, that at the election of a physician to the hospital at the next vacancy, the successful candidate should be appointed for a period not exceeding one year; a resolution in the propriety of which we concur, and although not adequate to meet entirely the emergency, shews the determination of the committee to use every means in their power to put an end to practices at once fatal to their Hospital fame and *usefulness*. One of the most amusing incidents of the meeting was the frank address of Mr. Guthrie, who avowed that feeling himself somewhat puzzled at the sudden flood of new governors into the hospital; he imagined that some surgeonship was in question, and that to protect his own interests, which might be in more jeopardy than he knew of—he had introduced some thirty of his friends as governors to be ready at the hour of need. Finding, however, how things stood, he pledged his honor to the committee that none of his nominees should vote in the approaching election.—ED.]

PAYMENT OF MEDICAL WITNESSES AT CORONERS INQUESTS.

THE act regulating this matter is the sixth and seventh of George IV. chap. 89. By the first clause the coroner is empowered to summon on an inquest the *legally* qualified practitioner who attended the deceased "*at* his death, or during his last illness." Or if deceased was not so attended, to summon *any* legally qualified practitioner "being in actual practice *in* or near the place" where death happened; and the coroner is further empowered at any time before the termination of the inquest to direct a *post mortem* examination, with, or without analysis of the contents of the stomach, the medical practitioner attending the deceased being prohibited to perform the autopsy, if oath be made before the coroner that he was partly or entirely instrumental in the death.

By the second clause, a majority of the jury are empowered to require that the attendance of any legally qualified practitioner or practitioners be ordered by the coroner, who, if he refuses, is made punishable as for a misdemeanour.

The third clause "requires and commands" the coroner to order remuneration to "the legally qualified practitioner" who "has attended upon any coroner's inquest, in obedience to any such order as aforesaid," and fixes the sum of one guinea for "attending *to give* evidence" if there be no *post mortem* examination; and of two guineas

for a *post mortem* examination of the deceased, either with or without the analyses, &c., conjointly with attendance to give evidence.

Clause 4 prohibits all payments for *post mortem* examinations where there has been no direction for such examination by the coroner; and clause 5 excepts from payment under this act, all witnesses who being the medical officers of any hospital, lunatic asylum, or any public medical institution, had the duty of attending the deceased person, the subject of any inquest.

By the sixth clause, a five pound forfeiture is enacted against medical practitioners who being duly served with the coroner's order, do not attend the inquest. Service at the house is service to the practitioner.

PHRENOLOGICAL SOCIETY.

On Monday Evening the usual meeting was held at the Rooms, Exeter Hall. After the minutes of the last meeting had been read by the secretary, T. Hewett, Esq. R.A., W. Topham, Esq., Middle-Temple, and Dr. Debout, of Paris, were elected Members of the Society. Dr. Elliotson, in alluding to the case of Cooper, which had been the subject of the last meeting's lecture said that the head was small, the organs of "Destructiveness" and "Caution" were very large, which must inevitably produce Revenge. He then remarked upon the curious mesmero-phrenological phenomena elucidated by Mr. Carstairs, of Sheffield, where the patient upon the organs of Time and Tune being touched, sang an air, and when Language was chafed added words to the tune. The other organs produced similar results, and this, under circumstances which precluded all possibility of collusion. He next entered into a clear detail of phreno mesmerism for the honour of the discovery of which, there was a sharp contest in America, between Dr. Collyer of Massachussets, and Dr. Buchanan of Louisville. By this discovery, the Doctor said, it is shown that during mesmeric sleep, one organ may be separately excited, and that also, at one and the same time an organ on either side of the cranium, may be simultaneously excited, thus presenting, as it were, two distinct minds co-existant with each other. Thus whilst one arm, should menace upon Combativeness being touched, the other, upon Veneration being excited, should be put forth to welcome. The president exhibited the cast of a young lady (æt. 18) in whom all the moral qualities were highly developed, and whom he had cured by mesmerism of severe epileptic fits. He observed that he had never been able to excite the intellectual faculties in this case, although he had repeatedly tried. He concluded his observations by announcing that at the next meeting, ladies would be admitted. Nothing of further interest occurred.

EXTRACTS FROM FOREIGN JOURNALS.

(Translated from the 'Berlin Medicinische Zeitung,' for the 'Medical Times.')

On the Relation of Affections of the Heart, with Acute Rheumatism. By Dr. Schlesier.—The merit of having drawn attention to the connection of inflammatory affections of the heart with acute rheumatism, belongs to the new French school of Bouillaud. The subject, as it deserves, has received proper acknowledgment from us; and it can escape no medical man who is familiar with the investigation of physical symptoms, how frequently inflammatory affections of the heart are complicated with rheumatic fever. Testa had, indeed, already shewn this relation, and the merit of priority properly belongs to him. But Bouillaud, to whom the stethoscope and percussion were at command, has been the first to make the fact profitable in practice. Much, that by the old physicians was considered as nervous rheumatic fever, and wherein the death of the patient was the consequence of an exciting method of treatment, is now acknowledged as pericarditis and endocarditis, and cured by bleeding. The occult inflammations of the heart, found in the bodies of those dying from the so called nervo-rheumatic fever, have ceased to be latent, since medical men have learnt by the use of the stethoscope, to discover inflammations, of which, on account of the want of subjective symptoms, and functional disturbances, no external signs appear. Affections of the heart, which so frequently accompany violent acute rheumatism, do not always depend on inflammation; but pure nervous affections of the heart arise in the course of rheumatic fever, disturb the functions of the heart, and bring forth the same complex symptoms in the subjective phenomena. As Bouillaud's opinion, and the antiphlogistic treatment based upon it, is so beneficial in the greater number of cases in which the co-existing affections of the heart are inflammatory, so must they be destructive where spasm of the heart complicates itself with the rheumatic fever, and calls forth the heart symptoms. Rare as these cases may be, in proportion to the inflammatory, yet is the fact certain that they do occur. The distinction according to the subjective and functional symptoms is impossible; here alone the physical signs may be able to give the solution, and on their employment depends the life of the patient. I had an opportunity of observing a very instructive case of this kind in January last, and believe it is not unworthy of publication.

A clothier, Kr., a pale, thin, and weakly man, had, in the latter end of December, much heated himself by a journey on foot, when an opportunity offered for him to ride home in a farmer's waggon; he had with great improvidence lain down in the open waggon, being very lightly clothed, and from weariness soon fell asleep. When he arrived at home, he was stiff in every limb, and was not able to move or stir himself. A violent fever came on, with very great pain, cough, side stitches, anguish, anxiety, and suffocation. I was called in on the 2d. January. The fever was strong, great heat, burning thirst, the pulse (120) small, hard, quick, the skin hot, and (they had given him elder tea for drink) covered with a profuse sour perspiration, urine crude, scanty, smelling sour and reddening litmus paper. He had not slept for two nights, light delirium, his sensorial functions in general not clear. He lay stiff on his back, without being able to move a limb. Every articulation, from the upper vertebra to the joints of his hands and feet, was attacked with violent rheumatic pains, the last reddened and swollen. Together with these, the patient suffered from short, painful cough, with slightly bloody sputa, stitches in the side, oppression, and short breathing, and frightful attacks of anxiety and suffocation. Auscultation shewed dry crepitation in wider extension in the right lung, with entire want of the normal murmuring respiration sound, and percussion gave a dull sound, while the heart with powerful palpitations and an anomalous impulse gave to the ear a vehement shock, and on the left of the sternum was perceived a rasping sound. One could labour under no doubt, that the patient suffered from acute rheumatism, with parenchymatous inflammation of the right lung, and inflammation of the pericardium, with sthenic reaction. Copious general and local bleeding, and the internal employment of digitalis, nitre, ant. tart., succeeded in the course of a few days in setting bounds to the inflammation of the thoracic organs, and in some degree moderating the violent pain of the joints. By the 6th of January, the heart and lung symptoms were removed, the heart stroke now only a little hastened, its impulse hardly raised above its normal state, the grating sound disappeared, and instead of the crepitation in the right lung, moist mucous rattle was audible. The attacks of anguish, anxiety, and suffocation had ceased. The patient expectorated well, the reactive fever shewed itself much moderated, in the character of erethism, the pulse was become soft, slow, and undulating; the urine less fiery, formed a crystallized sediment, but the cuticular secretion was yet raised above measure, and combined with purple eruptions upon the breast and back, to which the small hot room might well have contributed. The rheumatic affections of the joints of the vertebra had nearly disappeared, but the swelling of the joints with the pain yet continued with the same violence. The debilitated patient took ammon. carb. with ext. aconit.; and the continued disturbance of the nightly sleep, threatened a prejudicial influence upon the already disturbed sensorial functions, which was the more to be feared as the patient was not free from the suspicion of the abuse of spirituous liquors. From the danger, I endeavoured to increase the purple eruptions and perspiration; with the ammon. carb. I gave calomel grs. ij., opii. i. at night. By these means he went on quite as well as could be wished until the 11th. The fever had nearly quite yielded, heart and lungs completely free, the left hand quite painless, and in the feet and the right hand the rheumatism was so far mitigated by the lessened tumefaction that the patient might be considered as re convalescent, and this the more, as the sweating, quite contrary to my expectation, had ceased, from the use of the ammonia and opium, and a more moderate temperature of the room, and a light covering instead of the heavy feather bed. The eruption had dried up, and the urine shewed a copious critical crystalline sediment.

In the night of the 12th January, the 14th of the disease, the patient was seized with a violent attack of palpitation, anguish, suffocation, and apnœ, which lasted an hour. In the morning I found the fever again kindled, the skin dry and hot, the urine crude, and without sediment, yet no heart or lung symptoms, except a quickened beat of the heart. Towards night the above paroxysm renewed itself, while the fever reached a considerable height, and the palpitations came on with the same intensity and extension as before, the pulse (100) small and quickened; the local symptoms in the joints had nearly disappeared. I confess, that in the idea of a recrudescence of pericarditis, and impelled by the pressure of the circumstances, I had seized the lancet, and only delayed from reflection on the great weakness of the patient; I applied my ear to his chest, and I heard an extremely quickened stroke of the heart with a strong shock, phenomena which might be perceived by the applied hand and eye; but no trace of false sounds of the heart, and indeed neither grating sound, as characteristic phenomena of pericarditis, nor bellows sound, or rushing sound, as criteria of endocarditis, or rattle affection. Percussion gave even as little suspicion of exudation, which from the general distinctness and clearness of the heart pulse was not *a priori* to be thought of. From enquiries, I now first learnt he had suffered from great emotion of mind the day before; he had been judicially distrained. Now his situation was at once clear; instead of a fatal bleeding, he received a dose of opium and a blister on the chest; and by the use of infus. valerian with liquor elleri, repeated frictions

on the back with spir sinap, and a daily dose of opium, I succeeded in conquering the periodically exacerbating and remitting heart spasms, in the course of a few days, and in bringing on a normal crisis of the skin and urine, and giving life to the man who, for many days had been apparently condemned unconditionally to death. This case exemplifies the importance of the stethescope and percussion.

TO CORRESPONDENTS.

We may announce that we commence next week giving Dr. Marshall Hall's Lectures *(now in course of delivery at St. Thomas')* on the Diagnosis, Pathology, and Treatment of Diseases of the Nervous System—*a set, reported verbatim expressly for the* "Medical Times," *and carefully revised by the distinguished lecturer. This will form the best possible pendant to Professor Owen's Course, (the publication of which we have recently completed) on the Comparative Anatomy and Physiology of the Nervous System.*

Will C. tell us if all be right. If so, the parcel will be completed immediately.

Verus.—*We are perfectly indifferent about the journal. If the Mr. Renshaw spoken about, of whom* we *know nothing, be one of those who ruin themselves to please a whim, or gratify an antipathy, the loss of five or six pounds a week must be a mere bagatelle, especially if it be as our correspondent supposes, an affair of* credit.

Adscriptor.—*The M. B. of the Dublin University would be no protection for the graduates practising in England. Till, however, every unqualified man practising in England were prosecuted by the Company, we should think our Correspondent would not be intermeddled with, and that gives him "a long day."*

Dr. Fleming.—*A Correspondent, giving his name, sends us a circular, published by Dr. Fleming, in Douglas, the Isle of Man, which enlarges on the Doctor's abilities, giving in full testimonials written for him (apparently by Dr. W. Stokes, Sir Philip Crampton, Mr. J. T. White &c., backed by all kinds of statements as to who he is, who he served, and with what approbation. Perhaps Dr. Fleming may be unacquainted with the circumstance, and will, therefore, pardon our assuring him that this mode of procedure is not that which the decencies of society, or the rules of gentlemanly etiquette, allow.*

H.—*The Almanac (now stereotyped) continues on sale, price 4d. stamped 5d.*

Dr. Aldis' diagram has been received, but we are disposed to think that the written description is sufficiently clear. If Dr. A. thinks differently, we should be glad to see the block.

A number of Correspondents will find answers in our abstract of the Medical Witnesses Bill.

A Gloucestershire Subscriber *would meet with no great difficulty in passing the examination. The name, if successful, would be published as a matter of course. Under the circumstances, however, we should say* quieta ne movere. *If resolved to pass, the better way would be to arrange every preliminary through Mr. Belfour before coming to town.*

Mr. Wakeman's kind offer is gladly accepted; and if all our other friends would use their influence in securing us fresh subscribers among their personal friends, we should feel more and more strongly the conviction now animating us, that we belonged to a profession truly worth battling for. They would too (may we presume to say it?) do their friends a service—as us a favour.

The Cases of Mr. Moore, and Mr. Smith, and Communications by Potens vini, M.N. Cary, M. S. H. D. and Dr. Bennett, received.

Mr. Lugar *is thanked. We did not profess to give* all *the medical institutions. The remuneration for medical witnesses attending trials is two guineas a day. In taxing costs, however, or allowing expences, great discretionary power is exercised, and hence great discrepancies in amount.*

C. B.—*The order* was *received. To the other question we have got advice, and the answer is decidedly yes. Our Correspondent will find the abstract of the act in another page.*

Mr. Power's *note has been received, but as a general rule we do not print answers to us which have appeared first in the Dublin papers. If Mr. Power sends us one of his tooth-brushes, which "Her Majesty has done Mr. P. the honour to accept," we will give her Majesty, who does us the gracious honour of reading our journal, our humble and dutiful opinion as to the propriety of using it.*

T. F. A.—*Professor Chomel's Lectures were commenced in vol. 5, and finished with vol. 6. Dr. Scoffern's were inserted in various numbers of the same journal. Any number of vol. 5 or 6 may be had through any bookseller by order. And to other enquirers we may say the same of vols. 1 and 3. There are several numbers of vol. 2 out of print. Vol. 5 contains also Velpeau's Surgical Lectures.*

THE MEDICAL TIMES.

Saturday, December 10, 1842.

Did these bones cost no more the breeding but to play at loggats with them? mine ache to think on't.

Shakspeare.

A strict regard to public decency, — a vigilant protection over general health, is one of the most sacred debts which a Government owes its people. It is no speculative principle of right—no inapplicable theory of abstract good—but a social benefit, practical, tangible, vast; one of the highest boons of *assured* civilization, as one of its surest marks: and which, indeed, forms one of the main considerations which make the checks and limitations imposed by Civil Government, worth the acceptance of mankind. In France, where, thanks to Napoleon, social justice—a thing very different, though not opposed, to the subject's liberty—is higher than in any other country in the world, this important matter is a primary concern of the State; and forms the sole subject of watchfulness to an intelligent and well-remunerated corps of medical police. By whom, or how, is the duty discharged in enlightened England? Alas! we have only to read the report of the House of Commons on the health of towns, and that of Mr. Chadwick on the sanitory condition of the poor, to have the plain fact *demonstrated*, that, despite our inquiring commissioners on all imaginable subjects, and our unemployed State pensioners for every imaginable reason, there is not a public person in the empire to whom public decency, or public health, is a matter of the least official consequence; and that, to all intents and purposes, they are subjects of which, neither our code of national jurisprudence, nor our machinery of law administration, nor our system of general government, take the least possible cognizance! The morals, the feelings, the healths of the great bulk of British society are, in a myriad of unnoticed ways, at the mercy of any knave or fool who finds it his interest to speculate against them. Could anarchy leave our country in its *social* relations, we will not say in a worse or more perillous, but in a more *disgraceful* condition?

The subject involving public health and decency, to which we mean to direct public attention to-day, is one on which we have frequently dilated—the shocking atrocities of the London grave-yard system. Hitherto we have contented ourselves with general remarks, directed against a foul and horrible custom, with a view to some measure of curative legislation. But we appear, now, to accuse, to punish,—not solely to expose the system,—but to convict on clearest evidence, and point out to condign punishment—specifically—individually—by name, some of the worse than cannibals who have worked and profited by the atrocities. There is *policy* in this, as well as *justice*. The monster-evil is incarnate in its fautors:—to smite *them*, is to destroy it: and though the duty be invidious, there is crime in its neglect. In proportion as the Government is forgetful of its office, the more urgent becomes the interposition of the *public press*—that great atoner for all governmental deficiencies.

The first culprit we place at the moral bar of public justice—alas! that it is the only bar at which our laws will allow us to place him—is Mr. Joseph Davis, the sexton of the parish of St. Ann, Soho. Our charges against him are threefold. First, that he adopts a swindling and dishonest mode of arranging interments; secondly, that he connives at, allows, *orders*, for his own pecuniary profit, a most indecent, a most horrible, and revolting system of mutilating, chopping, sawing up, and stowing away the remains of the recently-interred dead; and, thirdly, which follows from the two preceding, that he for years has been foully and grossly offending against public health and decency. The grave-yard under Mr. Davis's care consists of about two acres; and when we state that the place was formerly entered by a descent of three steps, and now by an *ascent* of four, it is made *more* easy to imagine the immense amount of carnal decomposition pervading the whole upper strata. Twelve years since, it was full "as an egg," to use a grave-digging informant's term: but the ingenuity of Mr. Joseph Davis has contrived, since, to extract thousands on thousands of fees, by adding to the heap thousands on thousands of additional corpses. As the saving of space is, of course, in such a state of things, a primary consideration, Mr. Davis has adopted a plan of some ingenuity, which we now proceed to make known. Graves are opened by him on what the diggers call "speculation." It is a mode by which fourteen or fifteen coffins may be buried with the expenditure of little soil, and little labour, and yet give satisfaction to the surviving friends of each. A grave is dug twenty feet deep; some six or eight paupers are buried one after another, till twelve feet from the surface is reached—the grave being kept open ten or fifteen days or more, till disease, in its successive course of sad triumphs, has sent them the number required. Till this period, little ceremony is required; but as twelve feet is a depth for *respectable* interments—for fee-payers, in short—the economic arrangement can only be maintained by the aid of clever deception. Accordingly, a boarding is placed over the last pauper's coffin, a little of the clay is strewed over this, and it is

offered as a very eligible grave, newly-dug, and *single*, to the next person enquiring for a *purchased* grave. The respectable corpse, if the surviving friends be very anxious, is now covered a foot deep with clay, which is again thrown up to admit another tenant to-morrow; and so the deception goes on, till Mr. Davis reaches within about four feet of the surface, when four children are in succession deposited on the top of all—a process technically called, "putting them on the shelf"--when the grave is covered up and another 20-foot grave commenced elsewhere. If a party cognizant of this practice insists on a separate grave, he cannot be obliged with his wish, unless he consent to have a twenty foot grave, and pay about thirty shillings for extra grave digging. He leaves the ground with the consoling belief that he has, at personal sacrifice, secured an undisturbed resting place for his friend's last remains. Fond delusion! The corpse of the loved one has been covered with a boarding and a sprinkling of earth, and it will not be finally closed till eight or ten more corpses are added to the heap! We shall not enlarge on the shameless dishonesty and revolting inhumanity here evinced. The cruel deception played on the parties' moral feelings—the charges, as for fourteen separate graves, where the expense has been but for one—the indecency of such a money "speculation"—the public injury to the health of the neighbourhood of leaving the corpses exposed for weeks under a broiling sun or drenching rains; these are facts plain, undeniable, revolting, and for all their criminality, Mr. Joseph Davis is the responsible party.

But we are yet far from done with the dishonesty of this parochial functionary. Our readers need not be told that persons having liberty to place a stone over an interred corpse, must have purchased the right to the soil in perpetuity. Now, it is a common custom in this grave-yard for the men, under the direction of Mr. Davis, to remove these stones—the land-marks of the dead—from one position to another, in order to allow the grave-digger to possess himself of the grave so occupied, and appropriate it to the use of some fresh purchaser. The robbery involved in these customary transactions is the least evil: there are, besides this, the violation of the feelings of the survivors, whose most sacred memories and hopes, it may be, entwine themselves round the last abode of their cherished friend—the chagrin and bitter disappointment they must suffer, if they detect the cheat—the foul deception practised on them, if, less unfortunate, they do not—and, lastly, the grievous mistakes the transaction would lead to, if there were question of disinterment; considerations which might be added to without number, and enlarged on without measure, but which, alone, and without comment, stamp this infamous custom of gain, and low villainy, as one deserving of all infamy.

Now for our second charge—that Mr. Davis has been concerned in a wholesale system of mutilating the dead. In mentioning the smallness of the ground—its fulness long years since—the numerous interments that are yet constantly taking place—a moral necessity is shewn for such mutilations. Without them there could now not be a single inhumation in the ground. But we are not dependant on such deductions. We have the authority of *two workmen* who dug in the yard for years, that scenes take place in digging every one of the twenty-feet-graves we have mentioned, which defy, in their disgusting horror, everything that the imagination could conceive. Recently-interred coffins are frequently come in contact with—sometimes in tiers—the tenants of which are as perfect as on the day of interment. The work is not, therefore, stopped. A rope, an axe-mattock, a saw, a knife, a stove with shavings, are procured, and are thus used. The saw is to divide the coffin, if too new for the axe-mattock, an instrument peculiar to this kind of work. The knife is surgical — it is to shorten the corpse, by cutting through the joints. The *rope* being slung round the body, or a large portion, the corpse is drawn up to be "shoved"—our informants' word—into a hole dug for it by the side of the grave.* During this work of mutilation and butchery, the *stove*, filled with lighted shavings, is kept below to prevent suffocation from the escaping gases; the men being, meanwhile, kept in spirits by the abundant chewing of tobacco, and drinking of gin, supplied by the sexton. We have here supposed them to have come in contact with the whole length of a coffin in a state of good—we might say ordinary--preservation; but it often happens that the coffin, or tier of coffins, only *abuts* by a third or a fourth of its length into the newly constructed grave. What then happens? The saw—the knife—are in request. The coffin wood is thrown up above, and the "disjecta membra"—the head or legs, as it may be—are violently forced back with the shovel or mattock into the other and untouched part of the coffin; and the orifice being plastered over with dirt, no trace of the horrible circumstance exists! This is an ordinary occurrence of grave-digging—an occurrence of which Mr. Davis has been too frequently cognizant, and which two grave-diggers known to us can and *shall*—if asked—demonstrate the existence of, by putting their feet on the very spot, the scene and still existing testimony of these atrocities.

These are FACTS stated only in part, and these as briefly as possible to suit, not the magnitude of the abominations, but the limitations of our space; but we think that, thus slightly given, they furnish abundant evidence of the criminality of the person whom, in the discharge of our duty to the public, we have felt it necessary to fix in the pillory of social justice. Nameless and obscure as may be the culprit—countenanced and encouraged, as he may be, by higher offenders against decency—it would yet be neither just to allow such odious practices to pass unrebuked, nor wise—we have thought—to omit so favourable an opportunity of giving, in his punished person, a useful lesson to all who may feel tempted to imitate his example. In the absence of any legal tribunal at which he might receive the punishment he so richly deserves, we have fearlessly dragged him before that of the public—we have stated offences against him he dare not gainsay, and which certainly we should never have been foolish or wicked enough to charge against any man, unless urged on by public duty, and supported by irrefragable evidence.

We now leave Mr. Davis in the hands of his parish and the public; merely subjoining, as supporting the statements that have been made to us by grave-diggers who have long worked in the ground—the evidence of another, given before the recent Committee of the House of Commons. Edward C. Copeland gives us, in reference to this ground, the following information:

Do you think the occupation of grave-digging is very unhealthy?—I am sure it is; and I have seen them play at what is called skittles; put up bones, and take skulls and knock them down; stick up bones in the ground and throw a skull at them as you would a skittle-ball.

Who has done that?—Fox and a party who used to go there to assist him in digging.

Have you known of the handles and nails of coffins being taken away?—Yes, there have been a great many taken away off the coffins.

Who took them away?—Fox, the grave-digger; he died lately in Drury-lane.

Could the inhabitants, in looking out, see all this?—Yes, they could not be off it; for it is surrounded with back premises all round.

Have you heard of any leaden coffins being cut up?—I do not know that I have there; but I have known Fox take off the handles and take out the nails with a sort of crow-bar.

Did he keep them for his own use?—Yes, he sold them. What do they do with the bodies when they cut away the coffin wood?—They emaciate them; the flesh they leave in the ground, and take the bones to the bone house. I have seen them chopped up before they were a quarter decayed. About nine years this month, my father was laid there. I cannot answer whether he lies there now, or whether he is taken up and knocked about.

Suppose they came to quite a fresh coffin, what would they do?—*If it has been in three weeks, they would not mind cutting it in two. I have seen them not a quarter decayed before they have been cut to pieces with the pickaxes.*

We add, as elucidatory of this, the evidence of Bartholomew Lyons, who, having the fear of losing his situation before his eyes, was anything but a willing or accusing or untutored witness. However, the following facts came out; it will be seen how they bear on our statement:—

I have had graves 21 feet deep where I now work; I have got one grave now with three bodies in it; it is 21 feet from the commencement of it, and after I have got out a few hours and leave it open, the foul air will get in; it is 17 feet deep now.

Is the grave kept open?—It is not exactly open, there is about 3 feet of earth on the top of the coffins, and then it is covered over by boards, and then so much earth on the top of the boards.

* There is also a bucket used to carry up the more liquid part of the decomposed matter; its duties, however, often extend to the solids.

So that every time a body comes you open the 3 feet and deposit the coffin?—Yes, according to the size of the coffin, if it wil go down.

What is the custom that you adopt in digging graves?—These 20-feet graves are allowed by the board of vestry, and on purpose to make the ground last the longer, every fresh grave is to be sunk 20 or 21 feet, if we can get 21; we get it till we come to water, and then we cannot get any further. If we meet with any other coffin that cannot be removed, *we never touch it*;* but otherwise timber that has been down from 40 to 50 years, with nothing in it except the bones, we remove.

You remove everything that is not sound?—It is all decayed, the bones and all, *they have nothing on them*, and we sometimes break up the old coffins.

What do you do with the mass?—The bones we put in a bone-hole.

What do you do with the coffins?—We take that to the place where they steam the church, and burn the wood.

Who burns it?—The beadle burns it, I believe, what we do have.

What quantity do you get up in a week?—Where we dig one of these graves, *we may have three or four barrows-full*; that is where we have to dig a 20-foot grave; but there may be some graves where the coffins are decayed, and nothing in them but the bones, and then we may have HAD A DOZEN BARROWS-FULL, and that is chucked down to where the steaming place i, and the beadle burns them.

Do you usually find this gas and foul air coming to you from other coffins on each side of you?—At times, very soon after I have burnt it out, I shall have to burn it out again.

And if you were to stay there, what would be the effect?—It would kill me, or any one else.

In digging this depth and taking away the wood of these coffins, has it ever occurred to you that any bodies have fallen upon you? I never had one in a deep grave, but I had one once; before I was there a man of the name of Fox had the ground; I succeeded him; he is now dead; he was a bad character; he is dead about three weeks. I dug a grave on a Sunday evening on purpose to get ready for Monday; that Sunday evening, and it rained, I was strange in the ground at that time; and when I went to work on Monday morning I finished my work, and I was trying the length of the grave to see if it was long enough and wide enough, so that I should not have to go down again, and while I was in there the ground gave way and a body turned right over, and the two arms came and clasped me round the neck; she had gloves on and stockings and white flannel inside, and what we call a shift, BUT NO HEAD.

The body came tumbling upon you?—Yes, just as I was kneeling down; it was a very stout body, and the force that she came with knocked my head *against a body underneath*, and I was very much frightened at the time.

You were at the bottom of the grave, and as you were digging at the bottom, the body of this woman without a head fell upon you?—Yes.

From the side?—Yes, from the side.

Out of the coffin?—It HAD NEVER BEEN IN A COFFIN; it is supposed that they took the head off for the purpose of sale.

What depth were you down when this body fell upon you? About nine feet.

Might they not have cut through the head as they dug down?—No, this body was taken out of the coffin before; she only lay just on the top of the earth, a little covered over; if she had been buried any depth at all, three or four feet, she could not have fell on me, the shoring of the earth would have kept it up.

How many wheelbarrows-full of coffin wood do you say you take away every week?—Not every week, but when we are digging these deep graves I may take away a dozen barrows-full; taking it upon the average, I should say, that for every deep grave I should take a dozen large barrows-full of wood out of the grave.

What is your salary or perquisites?—I have no wages unless I do work, except that I have 18s. a quarter for doing the church bells; this week I have not earned a farthing yet; I have half-a-crown for every grown person I bury, and I have half the extra digging, if there is any extra depth, and *my master** has the other half.*

Do you mean to say that you would like to change?—I cannot stop there long; I suppose the grounds will be shut up; I have been there [now some years, and if I should happen to want anything, the gentlemen give it to me.]

* This, the witness now owns, is far from the truth, as is proved, indeed, by the subsequent part of his evidence.

* The sexton, Mr. Joseph Davis.

We shall next week have a few words on the Tabernacle Chapel and its Grave-Yard, Tottenham-court-road.

REVIEWS.

Food and its Influence on Health and Disease; or, an Account of the Effects of different kinds of Aliment on the Human Body, with Dietetic Rules for the Preservation of the Health. By MATTHEW TRUMAN, M. D., &c. &c. London: Murray, 1842.

This work is interesting more from the nature of the subject than the mode in which the subject is discussed. We have a great mass of information collected on the subject of aliment, which, though given in a very succinct manner, is both curious and important. The author seems to have aimed only at imparting what is known upon the subject, and never ventures upon the field of speculation, or shews the least tendency to originality of research. Yet the work is not unscientific; nay it is even likely to attain popularity with the public if not with the profession. Without following our author into all the details of his subject, we shall endeavour to place before our readers in a general way the most important features of the work. Our author defines food "to consist of all ingesta taken into the body by which nutrition is effected or assisted." We do not like this definition; it appears to us nonsensical and absurd. A wheaten loaf, though not eaten, is still food, and many things *taken into the body*, and which *assist* in effecting nutrition, can upon no sound principle be called food. A blue pill or a turpentine injection may improve the state of the digestive apparatus, and thus *assist* in effecting nutrition; yet we cannot live upon blue pills or turpentine clysters. Food is that which directly contributes to the nutrition of organized bodies; everything which does not directly contribute to this end must be excluded from the category. Hence we would exclude condiments and medicines, and everything that does not yield one or more of the proximate and oleaginous principles of animals and vegetables. Accoding to this last view, nutritive matters may be said to include only, 1st. proximate principles of animal substances—as fibrin, albumen, gelatine, osmazome, mucus, animal oils and fats; and 2dly. proximate principles of vegetable substances—as gluten, mucilage, farina or starch, sugar, vegetable oils. These proximate principles may be viewed as pure nutritious matter diffused naturally among animal and vegetable structures, and capable of being extracted from these textures either artificially or by the action of the digestive apparatus. The book before us shows not only the extended circle of animal and vegetable existence from which man draws his subsistence, but also the diversities of taste which different nations and races of men exhibit in their choice of aliment. The food of man is derived from every class of verebrated animals, viz., mammiferous, birds, reptiles, and fishes, and from two great subdivisions also of the invertebrated, the mollusca and insects. The food derived from the vegetable kingdom is more diversified in form than that from the animal; thus, we have not only seeds from which *bread*, the staff of life, is derived—as wheat, barley, oats, rye, beans, pease, &c., but we derive immense supplies of nutriment from tubers, roots, fruits, seed vessels, leaves, bark, pith, and the sap and juices of plants. One man's meat, as the Proverb has it, is another man's poison; and the abhorrence with which one set of men regard the aliment of another would seem to justify, in this sense, the application and truth of the adage. We can relish in this country a steak from the pope's eye of a fat ox, or a slice from a leg of five years' old mutton, but would feel rather *queasey* about dining on a shoulder of horse-flesh, even though garnished with savoury dog and cat sausages, and supported right and left with broiled rats and fricaseed moles; yet in Denmark and Sweden horse-flesh is sold publicly in the markets. Dogs and cats, as well as frogs and toads,* are eaten in Paris, and in China, rats and moles are used every day as articles of food. Verily we are a prejudiced people, and shall we never learn wisdom? Our author, as might be supposed, is an advocate for good cheer, and highly commends the practice so often followed in this country of commencing or terminating any important *commercial* transaction with a good banquet. He views the practice as a powerful motive to human exertion: we cordially agree, and would seriously recommend the learned author to extend his principle to *literary* transactions also, and we are sure we should then stand a fair chance of a good turtle and venison dinner from the author himself for our review of the next edition of his work—the present edition being an excellent *morceau*, or rather, a substantial lunch which is worthy, in sooth, of the rumination and digestion of our readers.

Case of Suicide, &c. By DR. ROBERT SPITTAL, F. R. S. E.

THIS is an interesting case in its medico-legal aspects. M. D, a washerwoman, aged twenty-seven, married and having two children, was committed to Edinburgh prison. M. D. shewed symptoms of delirium tremens on the day of committal; on the next seemed well and composed, but towards the evening was found lying on the floor dead, with her throat horribly cut, a jug broken in pieces lying by her side, one portion all bloody. The cell in which deceased was found was locked, as was customary, during service. The blood spilt was great; there was much in the cell-pail (as if deceased leaned her head over it) and in one of her shoes which was on, the other off; her hands were a little bloody, and clothes, particularly about the neck, &c. On examination, the neck was found streaked and marked with dry blood; shewed an irregular wound in the front of the trachea, extending from the lower edge of the cricoid cartilege downwards for more than an inch, and being about an inch wide. The edges were abrupt and had a rugged appearance, and altogether there was no doubt that the deceased, who was of irregular habits, and in the depressed state of mind of all persons who, accustomed to ardent liquors, find themselves in moments of adversity entirely shut out from their usual stimulus, had committed suicide with one of the sharper portions

* See Duchatel.

of the broken jug. The singularity of the case was, that some window glass and an iron spoon (instruments of more *obvious* lethal power) were lying unmoved on the cell-window. The immediate cause of death offers here some little difficulty; but we should be disposed, all circumstances considered, to agree with the author, and attribute it to the hæmorrhage, rather than to the entrance of air into the circlation.

ENGLISH PATENTS, MORE OR LESS CONNECTED WITH PHARMACY, CHEMISTRY AND MEDICINE GRANTED IN 1841.

Armes, John, Plymouth, painter, for a new and improved method of making paint from materials not before used for that purpose.—January 16.

Baillieu, William, Gloucester-street, Queen-square, musician, for improvements in apparatus to expand the human chest.—Dec. 23.

Barratt, Oglethorpe Wakelin, Birmingham, metal-gilder, for certain improvements in the precipitation or deposition of metals.—Sept. 8.

Bucknell, William, Westminster, gent., for improvements in applying heat for the purpose of hatching eggs; which improvements are also applicable to other useful purposes where heat is required.—March 22.

Burnell, John, the younger, Whitechapel, manufacturer, for improvements in the manufacture of leaves or sheets of horn, commonly called lantern-leaves, and in the construction of horn lanterns.—November 2.

Chesterman, Wm., Burford, Oxfordshire, gent., for improvements in filtering liquids.—June 23.

Clark, Thomas, Professor of Chemistry in Marischal College, Aberdeen, for a new mode of rendering certain waters (the water of the Thames being among the number) less impure and less hard for the supply and use of manufactories, villages, towns, and cities.—March 8.

Daniell, Joseph Clisild, Tiverton Mills, Bath, for improvements in the manufacture of manure, or a composition to be used on land as a manure.—October 7.

Dean, John, Dover, Chemist, for improvements in preparing skins and other animal substances for obtaining gelatine, size, and glue, and in preparing skins for tanning.—February 23.

Drew, Joseph, the younger, St. Peter's Port, for an improved method of cutting and rolling lozenges, and also of cutting gun wads, wafers, and all other similar substances, by means of a certain machine designed by him, and constructed by divers metals and woods.—September 6.

Dyer, Charles Bunt, Pary's Mine, Anglesea, mine agent, for an improved method of obtaining paints or pigments by the combination of mineral solutions with other substances.—March 16.

Elain, Alfred, Huddersfield, surgical-instrument maker, for improvements in apparatus or instruments for the relief and cure of Procedencia and Prolapsus Uteri.—September 20.

Evans, George, Dorset-place, Marylebone, for an improvement or improvements upon trusses for the relief of hernia.—March 29.

Fanshawe, Henry Richardson, the younger, Hatfield-street, Surrey, chemist, for improvements in curing hides and skins, and in tanning, washing, and cleaning hides, skins, and other matters.—June 10.

Furnival, John Bradford, Street Ashton, farmer, for improvements in evaporating fluids applicable to the manufacture of salt, and to other purposes where evaporation of fluids is required.—Oct. 20.

Furnival, James, Warrington, currier, for an expeditious mode of unhairing, mastering, and tanning various descriptions of hides and skins.—March 29.

Goldner, Stephen, West-street, Finsbury-circus, merchant, for improvements in preserving animal and vegetable substances and liquids.—March 8.

Gunter, Henry, Cullum-street, Fenchurch-street, merchant, for improvements in preserving animal and vegetable substances.—January 6.

Hancock, William, jun., King-square, Middlesex, accountant, for an improved description of fabric suitable for making friction-gloves, horse-brushes, and other articles requiring rough surfaces.—February 3.

Harwood, John, Great Portland-street, gent., for an improved means of giving expansion to the chest.—October 7.

Haughton, John, Liverpool, clerk, for improvements in the method of affixing certain labels.—June 19.

Henderson, Robet, Birmingham, china-dealer and glass-stainer, for certain improvements in apparatus for heating and lighting apartments, and for other like purposes.—Dec. 9.

Hills, Frank, and George Hills, Deptford, manufacturing chemists, for certain improvements in the manufacture of sulphuric acid and carbonate of soda.—April 15.

Hompesch, Theophile Antoine Willhelme, Count of, Mivart's Hotel, Brook-street, Middlesex, for improvements in obtaining oils and other products from bituminous matters, and in purifying and rectifying oils obtained from such matters.—Sept. 4.

Laming, Richard, Gower-street, Bedford square, surgeon, for improvements in the production of carbonate of ammonia.—March 15.

Lee, John, Newcastle-upon-Tyne, manufacturing chemist, for improvements in the manufacture of chlorine.—August 4.

Lejeune, Jules, North-place, Cumberland-market, manufacturing-chemist, for a means of condensing and collecting the sulphurous and metallic vapours which are evolved in the treatment by heat of all kinds of ores.—November 4.

Moleyns, Frederick de, Cheltenham, gent., for certain improvements in the production or development of electricity and the application of electricity for the obtainment of illumination and motion.—August 21.

Normandy, Alphonse Rene Le Mire de, Red-cross-square, Cripplegate, doctor of medicine, for certain improvements in the manufacture of soap.—Sept. 8.

Parkes, Alexander, Birmingham, artist, for certain improvements in the production of works of art in metals by electric deposition.—March 29.

Pattinson, Hugh Lee, Bensham-grove Gateshead, manufacturing chemist, for improvements in the manufacture of white lead, part of which improvements are applicable to the manufacture of magnesia and its salts.—September 21.

Payne, Charles, South Lambeth, chemist, for improvements in preserving vegetable matters where metallic and earthy solutions are employed. July 9.

Pinkus, Henry, Maddox-street, St. George's, Hanover-square, for an improved method or methods of applying electrical currents, or electricity either frictional, atmospheric, voltaic, or electro-magnetic.—May 14.

Shanks, James, St. Helen's, Lancashire, chemist, for improvements in the manufacture of carbonate of soda.—May 27.

Thomson, Anthony Todd, Hind-street, Manchester-square, doctor of medicine, for an improved method of manufacturing calomel and corrosive sublimate.—March 8.

Wheatstone, Charles, Conduit-street, gent., for improvements in producing, regulating, and applying electric currents.—July 7.

Young, James, Newton-le-Willows, Lancashire, chemist, for certain improvements in the manufacture of ammonia and the salts of ammonia, and in apparatus for combining ammonia, carbonic acid, and other gases with liquids.—November 11.

FOR INVENTIONS IN FOREIGN COUNTRIES.

[Arranged Chronologically.]

January 11. For improvements in impregnating and preserving wood and timber for various useful purposes.—Uzielli, Matthew.

January 26. For improvements in evaporating fluids, applicable to the manufacture of salt, and to other purposes where evaporation of fluids is required.—Furnival, John Bradford.

February 15. For improvements in obtaining a concentrated extract of hops, which the inventor denominates "Humuline." — Newton, William Edward.

February 22. For improvements in the process of and apparatus for purifying and disinfecting greasy and oily substances or matters both animal and vegetable.—Newton, William.

March 8. For improvements in preserving animal and vegetable substances and liquids.—Wertheimer, John.

March 17. For improvements in the manufacture of the carbonates of soda and potash.—Clough, William Thompson.

June 26. For improvements in producing and applying heat.—Poole, Moses.

July 13. For improvements of steam-baths and other baths.—Poole, Moses.

July 21. For certain improvements in the production of sal-ammoniac and in the purification of gas for illumination.—Philippi, Frederick Theodore.

November 9. For certain improvements in the production of ammonia.—Newton, William Edw.

[From *Prichard's List of Patents for* 1841.

ROUGH REPORTS FROM GUY'S HOSPITAL

Rupture of the Cephalic Vein with Laceration of the Biceps, and Treatment by Transfusion.

John Chart, carman, æt. 33, maimed, admitted into Guy's Hospital, Nov. 19, 1842, at 8, P.M. He was thrown from his horse, and the wheel of the dray passed over his arm and body, from behind, forwards. Profuse bleeding immediately took place, which was not restrained till his admission into the hospital. His habits of life had been regular, and his general life good. A contused wound over the front part of the right arm, partly tearing asunder the biceps and dividing a large vein, supposed to be the cephalic (?) from the manner in which the accident occurred, rolling the biceps inward and consequently allowing the basilic to lie underneath A roller was applied round the fore-arm, from the wrist to the wound, and cold lotion applied.—20th, slight oozing took place during the night, but nothing of importance.—10, A.M. Swelling of the limb had taken place during the night, and was extremely painful. The bandage was then removed and cold water applied.—6, P.M. Great effusion of blood from the elbow to the shoulder-joint and under the pectoral muscle, —9, P.M., Great depression; and it was deemed advisable to tie the vein, but the bleeding shortly after ceasing and the ecchymosed appearance not spreading, that operation was not performed, the wound, however, was enlarged. —11, P.M Mustard poultice, Hyd. Chlorid, p. opii. *a a* grs. ij. s. s. As it was evident he could not live much longer, transfusion was had recourse to, and two gentlemen immediately consented to supply the fluid. The left basilic vein was consequently laid open, and 18 or 20 ounces of blood injected, which produced symptoms of marked improvement; his pulse became stronger, and his countenance improved; previous to the operation he vomited once.—21st. 4 A.M. The symptoms of improvement did not increase, but remained at par.—6, A.M. Vomiting recommenced and continued till his death with but little intermission. His face became exceedingly pale and anxious. Effusion of blood in fore-arm not increased. At 8 A.M., slight motion.—10 A.M. Hyd. Chlorid. gr. i. p. opii. gr. i. s. s. brandy, beef tea and arrow-root.—11. A.M. Pulse scarcely perceptible; hurried respiration; eyes suffused: part of injection returned; enema.—1. P.M. Several large vesicles appeared over the shoulder-joint.—2½. P.M. ed.

On Dit.—Two gentlemen occupying the situation of dressers at Guy's, having quarrelled and exchanged blows in the Square, went out by agreement on Wednesday noon into St. Thomas Street, and enjoyed all the pleasures of a pugilistic encounter, surrounded by an admiring crowd.

PERISCOPE OF THE WEEK.

Extraordinary Case of Twins.—Dr. Jameson, of Dublin, was called on the 3d of April last to a lady, thirty years of age, the mother of four living children, who had been delivered on the preceding 13th of February of a son, by a midwife in the county of Wicklow. On that occasion the labour was completed in four hours, and the placenta came away ten minutes afterwards without any subsequent hæmorrhage; the patient recovered from this labor, and employed herself in her avocations, but remarked that the abdomen had not much decreased in size, which she attributed to bad swathing; general health good, supply of milk sufficient.—When Dr. Jameson was sent for, she was suffering from severe pains through the abdomen, recurring at uncertain intervals, and lasting about five minutes. On examining the abdomen during a pain, a firm, hard tumor was felt, reaching as high as the umbilicus, which became softer on the subsidence of the pain, and which was at once conjectured to be the gravid uterus. On applying the stethoscope over the tumor, after some difficulty Dr. Jameson thought he heard a placental murmur in the right iliac fossa, but no sound of the fœtal heart, from which he suggested the possibility of his patient's being with child, and then in labor. This idea, from the circumstances previously detailed, was at once repudiated, and a vaginal examination refused; but a short time afterwards, while the doctor was conversing with the husband, he was hurriedly summoned to the bedside of his patient, who told him something was coming from her. On making the examination during a pain, the head of a small child was found presenting with the membranes complete; and on the recurrence of another pain, the child, membranes, and placenta, were expelled together. The bag, which contained very little liquor amnii, was immediately opened, and it was found to contain a dead male child, at about the sixth month of gestation, shrivelled and dark, but not at all putrid or decomposed, and between eight and nine inches long. The cord was small, easily giving way under the fingers, but the placenta appeared to be fully as large as one belonging to a full-grown fœtus and healthy. The last time the patient menstruated previous to this pregnancy was in the latter end of April, 1841, and as she was confined on the 13th of February last, forty-two weeks must consequently have elapsed between the last period of menstruation and the birth of the living child, forty-nine weeks between the mentrual period and the evulsion of the dead fœtus.

Purulent Infection.—A man who died recently at la Charite, from an injury of the head, had fallen on his head, and become insensible. He was carried to the Hotel-Dieu, where he found himself so much better the next day that he left immediately; but he had scarcely reached home before he experienced tremblings and symptoms of an accession of fever, for which he was admitted into la Charité under the physician's care. The fever closely resembled an intermittent, and he was treated accordingly with the sulphate of quinine. He returned home some days afterwards, but continuing to experience rigors, he placed himself under the care of M. Velpeau, who at once pronounced a very different prognosis, and stated that the case would terminate fatally. In addition to the symptoms of intermittent fever, the man was continually feverish, with a dry tongue; he was in a kind of stupor, complained of dull pains in different parts of his body, especially in the epigastrium and right hypochondrium, in which there was a large abscess. There was also a large wound on the head, suppurating badly; the cranium was laid bare, and fractured. The man, instead of labouring under intermittent fever, was affected with purulent infection, and died soon afterwards. On examination of the body the skull was found to be fractured, but the broken bone was not depressed. The liver contained several large purulent *foyers*, and some were seen in the lungs. There was also partial peritonitis near the situation of the liver. The tremblings and rigors, which were looked upon as the forerunners of an intermittent fever, are, according to M. Velpeau, the indication of the introduction of a poison into the economy. Thus, when after a painful catheterism, such symptoms occur, practitioners say that the passing the catheter has been followed by one or more attacks of ague. This pretended ague, according to the professor, is no other than the indication that, under the influence of a modification with the mechanism of which we are not well acquainted, a certain quantity of urine has penetrated into the economy. It is an urinary affection, and so far from offering only the importance of an ephemeral fever, is on the contrary, a very dangerous symptom, for in many cases it indicates a fatal termination. M. Velpeau gives six or seven examples of this kind.—Sometimes these rigors are followed by arthritis of the knees, feet, and wrists, and suppuration is established with extraordinary rapidity in those articulations. All these symptoms arise from the same cause, the absorption of a poison into the economy, and intermittent fevers themselves have not any other origin. The trembling, which is the first period, is the sign of the introduction of the miasma into the humours. Most frequently, however, this poison is not so violent but that the economy can free itself of it; but, in certain cases of typhus, death follows very rapidly Purulent infection has been said to be nothing else than phlebitis, but M. Velpeau, has found the veins not inflamed in a great many cases where the purulent infection was very marked. It is certain that the pus is conveyed with the blood into the parenchymatous organs. where it acts in two ways; it is either transported *en masse* into the organ, and forms a deposit there, or else some globules only are deposited, which create irritation in the tissue, produce inflammation, and an abscess forms; it is very certain that this phenomenon may take place without phlebitis. The veins are sometimes healthy, sometimes they are inflamed at a distance from the primiti e collection, and it is not necessary to suppose the existence of phlebitis to explain this absorption. The veins which are near the pus may absorb it, and carry it to a distance. There may also be a genuine imbibition, and the inflammation which is so commonly observed may be only the effect, not the cause, of the absorption.

Abscess of the Liver.—The following case is given by Dr. Placida Portal, of Palermo. Ginseppi Capozzi, twenty five years of age, of a bilious temperament and weak constitution, after having had attacks of ague, and after having been cured of syphilis by mercurial treatment, experienced a feeling of weight in the region of the liver, attended with emaciation, constipation, yellow tint of the skin, and pains in the joints. On the 15th of November, 1839, a tumour was discovered in the right hypochondrium, presenting the following appearances:—It began under the right false ribs, caused the xyphoid cartilage to project very much, and threw its point forwards; it also occupied the umbilical region, and extended down to the middle of the right side; at its lower part it was prominent, hard, and painful, with deep-seated and obscure fluctuation; the skin that covered it was of a natural colour. The patient complained chiefly of pain and weight in the right hypochondrium. The abdomen was hard and distended in the epigastric region, but soft in the hypogastrium; the enormous size of the tumour prevented the patient lying on his back, and forced him to bend forwards when he was sitting He had anorexia and dyspepsia, and occasionally was troubled with nausea and vomiting of a mucous matter; the tongue was covered with a thin white coat; the face was of a deep yellow colour; the pulse, small, contracted, and slow; cough dry and fatiguing; urine scanty and limpid: the legs œdematous; and he had feverish symptoms, with rigors and burning thirst. Under these circumstances, Dr. Portal diagnosed abscess of the liver, which he opened as follows:—He introduced a trocar into the most prominent part of the tumour in the right hypochondrium, where the skin appeared to be thinnest, about two fingers' breadth below the ensiform cartilage. On the withdrawal of the trocar, a thick, very fœtid, brownish-coloured pus was discharged. Having next introduced a cannelated sound, he incised longitudinally from without inwards the linea alba and the fibres of the rectus abdominis; then introducing the finger, he dilated the opening to about four inches. An enormous quantity of pus was discharged, containing an infinite number of hydatids of different dimensions, and a pseudo-membrane a foot and a half square. A piece of linen, with simple cerate spread on it was introduced into the wound, a pledget of lint and compresses laid on it, and a body bandage placed over all. The patient was then put to bed and laid on his left side. Four hours after the operation the patient experienced severe pain, attended with high fever; the pain was relieved by the application of thirty leeches, and three poultices successively over the abdomen. He passed a good night, and the next day a large quantity of pus mixed with bile was discharged A canula of gum elastic, five inches long, with a calibre of five lines, was fixed in the opening to facilitate the spontaneous vacation of the pus. Forty-six days after the operation, the wound had completely cicatrised.

Hydropathy in England.—Dr. Hastings publishes the following letter of a gentleman, who purchased his experience at the establishment at Malvern. "As for hydropathy as a general specific, it is utter nonsense. Gout and rheumatism are relieved, and some cases of fever it succeeds in, and people of long standing habitual constipation seem to have benefitted, but in asthma, tic, acute diseases, dropsy, apoplexy, or surgical cases, it is of course an utter failure. Good is no doubt done by early hours, exercise, and abstinence, but a cure never or rarely effected. Dr. —— is a conceited, impudent, off-hand sort of a person, and he goes about telling everybody of his success and wondrous cures. He states he has cured Lord ——, but this I do not believe to be the fact. The general class of patients here are old Indians from Cheltenham, hypochondriacal ladies, and dyspeptics. What is useful in hydropathy will be added to general practice, and then it will follow St. John Long, mustard-seed, and brandy and salt. The system is new, and may, perhaps, last a year or two. On my arrival here I was subjected to the sweating process—four blankets and a feather-bed over me—and in ten minutes I felt giddy, the room ran round, lights came before my eyes, and just before consciousness departed I flew out of bed. Once more I tried it with a similar effect, adding vomiting to all the other disagreeables. Had I had a fit the danger

would have been imminent. I therefore gave up all idea of submitting to further mountebank folly. The whole affair is a humbug, as far as its being a universal cure."

Urinary Fistula.—M. H. Larry communicates a very curious case of urinary fistula cured by operation. The subject of the case was a female who had been long subject to urinary fistula situate beneath the umbilicus; the disease originated in inflammation of an ovarian cyst, containing hair, which had communicated on one side with the bladder, and on the other with the parietes of the abdomen. The contents of the cyst, composed of viscid and purulent matter, hairs, and calcareous concretions, had been discharged, at various times from both orifices. At length a large calculus formed in the bladder, and, getting entangled in the opening of the urethra, had forced the urine to issue, almost constantly, through the fistulous orifice in the abdomen. After considerable reflection, M. Larry determined on performing an operation founded on the principle of lithotomy, as practised above the pubes. With this object he divided the fistula freely inferiorly, exposed the cyst, extirpated a tumour to which adhered a long lock of hair, and followed the latter into the bladder, where it formed the nucleus of the stone, which he removed. The immediate effects of this very formidable operation were comparatively mild, and the patient recovered perfectly.

Engorgement of the Uterus.—Dr. Clement Ollivier, of Angers, speaks strongly against the use of differently shaped pessaries, which are employed indiscriminately for prolapsus uteri, without paying attention to the cause of the prolapsus, which, according to Dr. Ollivier, is nothing more than engorgement. Dr. Ollivier considers masturbation one of the most frequent causes of this affection in young girls, with whom it is very rare. By gradually inducing disorder in the uterine functions, it gives rise at first to a spasm of the organ, which affects the secretion of the menstrua; on the other hand, this excitement, if frequently repeated, finally brings on a more or less intense sanguineous congestion, which gives rise to a kind of impermeability of the uterine parenchyma, caused by a slight inflammatory affection; then the dysmenorrhœa, at a latter period, becoming habitual, induces amenorrhœa, which ultimately determines more dangerous diseases. Sterility is always an inevitable result, unless the diseased state of the uterus being arrested, allows those portions of the viscus which continue healthy to perform their functions; the catamenia may then reappear, but are almost always accompanied by uterine colics; the matrix may recover its powers of conception, but during gestation a period arrives when the uterus, not being able to enlarge freely, on account of the inflammatory action it has undergone before conception, reacts upon the product it contains, and almost always determines an abortion; in this way the pregnancies of women affected with morbid conditions of the uterus almost always terminate.—Masturbation, in causing a disordered condition of the entire uterus, produces more frequently an engorgement of the body of the organ rather than of the neck, whilst an exactly contrary condition obtains in women who have connection with men. In virgins the affection of the body of the uterus is more frequently found, that of the cervix uteri more rarely. Dr. Ollivier mentions, among other causes of engorgement of the uterus, the irritation of the sexual organs by primary connection, a cause of irritation of the organ the more dangerous, that it has hitherto escaped the notice of medical men, either because they do not attach sufficient importance to it, or because women conceal from them the knowledge of their illness, notwithstanding the sufferings they endure.—The dysmenorrhœa, which almost always follows abortions, is the result of an inflammatory engorgement more or less considerable, and susceptible of cure; this engorgement is the cause of the sterility that follows miscarriages.

The Starch Apparatus for Fractures.—One great objection to this apparatus has been, that when once put on, it remains a hard case round the limb, allowing no room for the necessary degree of tumefaction, and consequently endangering the safety of the member by inducing gangrene; and that, as the parts were hid from view, no timely warning was afforded of such accidents. According to the Dublin Journal, the inventor, M. Seutin, has now obviated this objection. He first applies a calico roller, moderately firm, round the leg; no starch put on the inside of this bandage, as it would stick in the hairs, and prove unpleasant to the skin when it hardened. After it is applied some starch is smeared along its surface; wherever pressure is wished to be avoided pledgets of soft lint are put; a soft pasteboard splint, a little starched on the inside, is then placed on each side of the leg, and then one behind the part about the heel and the hollow of the tendo Achillis being well stuffed with lint; a pasteboard splint is also put in front. These are secured by a bandage smeared with starch, the end of the bandage being turned down and stuck in front, so as to be easily found. More starched bandage was applied, till the whole was a firm and smooth case. This should be left for twenty-four hours; when it has become quite dry, it is then slit down along the whole front of the outside, in the space between the tibia and fibula, down to the end of the foot. When the sides of the opening are held aside, the state of the limb can be examined. If it is found to press too much on any part, a little lint can be inserted, so as to raise the apparatus from the place pressed on; should it be desirable, any part of it covering a wound, &c., can be cut away, to allow the proper dressings to be applied, and the discharge to be removed. Long bandages are preferred wherever it is requisite to establish a regular compression, and that the lifting up of the injured part may not entail inconvenience to the patient, sharp pain, derangement in the coaptation, &c. Short bandages, are reserved for contrary cases; they are disposed generally in three planes; it is between the layer in contact with the skin and the middle layer, that the pasteboard splints are generally placed; short bandages are especially employed in lesions of the pelvic extremity. The length or breadth of the bandages is proportioned to the part which ought to be covered with them. Folds should be repeated as seldom as possible, and never on bony eminences or excrescences, which should be defended by layers of wadding, lint, or some other such material, besides the bandage. It is important to leave uncovered the ends of the fingers or toes, whose variations of color and of temperature furnish a sufficiently just measure of the analogous changes of the other parts of the limb covered by the bandage. The compression exerted by this apparatus ought never to reach to that degree of violent constriction which practitioners, as little familiarised with M. Seutin's method as with the general principles of compression, have believed to be necessary for the resolution or prevention of inflammation. Compression, as understood by M. Seutin, ought to stop at a gentle methodical pressure, sufficient to moderate the afflux of blood, but not to stop it—a pressure which, in many circumstances, at the instant of its application, is only retentive, and which never acts on the soft parts, so as to be able to induce mortification in their tissues. The pressure should always be made to act from the extremities to the centre as evenly as possible, care being taken to avoid its immediate action on bony or tendinous prominences, excrescences, &c. The starch apparatus dries in the course of from thirty to forty hours after its application, but its desiccation may be aided by the employment of artificial heat, if needed, which, however, is better avoided, if possible. Unless the patient complain of pain, or much uneasiness in the injured limb, or the surgeon entertains fears of the state of the soft parts, it would be as well to defer the section of the bandage to the second or fourth day, when, if the apparatus fulfil the views proposed, it is made secure again with a starched bandage; if it exercise too much pressure, the edges must be separated, the interval being filled up with a little softened pasteboard; the exterior surface is then to be smeared with starch, and the apparatus surrounded by a starched bandage, very little compressed. Folds and plaits that press the skin irregularly are to be removed; the pieces that exercise injurious local pressure are to be wetted slightly with water; pieces of lint are to be inserted where necessary, and the whole to be surrounded by the starch bandage, care being taken to make a daily inspection to see that all is right. If the apparatus appear defective in any particular, it should be removed, having been previously wetted with tepid water, and replaced by another, less objectionable.

Calculus Vesicæ.—M. Dieulafey publishes several interesting cases with respect to the shape of the calculus in the bladder. He performed the lateral operation on a child, five years old, in whose bladder he previously had discovered a calculus by means of catheterism, the presence of which he also ascertained by passing the index finger into the bladder, but which he could not touch with the forceps when he had passed them into the viscus. The instrument was frequently passed into the bladder, but each time unavailingly; he found it impossible to lay hold of the calculus, the presence of which he had nevertheless fully determined by the finger and the catheter. The surgeon was very much perplexed by this, when his assistant opening the blades of the forceps to clean them, discovered a calculus, about the size of a little pea, in the midst of clotted blood in the teeth of one of the blades. During the manœuvres of the operator, the calculus had lodged in the teeth of the blades, and as it was not large enough to prevent their closing, its taking that position had not been noticed. The operation having thus terminated, the little patient speedily recovered; M. Dieulafey drew the conclusion, that, in every case of lithotomy, the blades of the forceps should be examined after they have been withdrawn from the bladder. In another operation of this kind, the same surgeon, after having ascertained the presence of the calculus in the bladder, introduced the forceps several times without being able to seize it. The blades were examined each time they were withdrawn from the bladder, but they did not contain the calculus, which was ultimately discovered in front of the incision, in a kind of cavity which opened in the membranous portion of the urethra, where its narrow and elongated form had allowed its entrance. The painful and fruitless researches which had been had recourse to, were not attended with any injurious results. In another child, scarcely two years old, although the stone could be felt with the finger, it could not be seized with the forceps in whatever direc-

tion they were inclined. The calculus was situated behind the prostate upon the trigonum of the bladder, and it was necessary to use the curved forceps to enable the operator to extract it. The calculus was perfectly round, of the size of half a franc in diameter, and exceedingly thin. M. Dieulafey attributes all the difficulties of the operation to the peculiar shape of the calculus.

Antidote for Corrosive Sublimate.—M. Mialhe says he has discovered from experiments that hydrated proto-sulphuret of iron, a perfectly inert substance, instantly decomposes corrosive sublimate; protochloride of iron and bisulphuret of mercury, two inert substances, are formed, from which valuable property he designates this sulphuret of iron as the best antidote for the violent poison alluded to. When a small quantity of bichloride of mercury is taken into the mouth, there is speedily experienced an insupportable and characteristic metallic taste. If now, the mouth be gargled with the hydrated sulphuret, in a thick state, such as it should always be used in, the mercurial taste is removed as if by enchantment. The antidote is not limited in its effects to the mercurial salts, it is equally useful in counteracting the deleterious operation of several other metallic salts, especially those of copper and of lead. The following is the mode of preparing the hydrated proto-sulphuret of iron:—Dissolve any quantity of pure protosulphate of iron in at least twenty times its weight of distilled water, deprived of air by boiling, and precipitate the iron with a sufficient quantity of sulphuret of sodium, dissolved also in distilled water, deprived of air. Wash the protosulphuret thus obtained with distilled water, and preserve it in stoppered bottles, filled with boiled distilled water. Although the preparation of this sulphuret of iron is very simple, and may be effected in a few minutes, yet it would be desirable to keep it always prepared, that no time may be unnecessarily lost in any case of poisoning. The precaution of preserving this sulphuret out of contact of the air, must be strictly observed, as it has a great tendency to pass into the state of sulphate.

Black Drop.—The following is said to be the original recipe published by Dr. Armstrong, for black drop:—Take of Opium lbss., Good Verjuice Oiij., Nutmegs ℥iss., Saffron ℥ss. Boil to a proper thickness, then add two spoonfuls of yeast, set the whole in a warm place near the fire, for six or eight weeks, then in the open air, till it becomes (the consistence of) a syrup, when it is to be decanted, filtered, and bottled up, with a little sugar added to each bottle; one drop equals three of tincture of opium.

Tests for Arsenic.—Meillet prepares pure zinc by first fusing commercial zinc and throwing it into hot water, by which it is obtained in the form of large grains. These are placed in a Hessian crucible, with alternate layers of saltpetre, equal to a quarter their weight; the crucible is covered and heated until the nitre burns and the zinc is perfectly fused; the slag is then removed, and the perfectly pure zinc poured out. Fordos and Gélis have remarked that the purest zinc, when treated with strong sulphuric acid, gives off traces of sulphuretted hydrogen, arising from the reduction of the sulphuric acid. Hydrochloric acid, which, as is well known, often contains sulphurous acid, also gives traces the same gas, evidently derived from the of sulphurous acid. Chevallier had already proved that Marsh's apparatus is not applicable to testing for arsenic when it is in the form of sulphuret; and consequently if much sulphuretted hydrogen were formed, the whole of the arsenic present would be converted into sulphuret, and the spots obtained will be yellowish. The spots obtained by Danger and Flandin are referable to this cause; the organic matters not being completely carbonised, sulphite of ammonia was produced; the sulphurous acid by its reduction gave rise to sulphur, and consequently sulphuret of arsenic, and the spots were therefore yellow. Wackenroder has proposed several methods to determine whether the spots obtained are owing to arsenic or to antimony; the only one which need be noticed depends on the crystalline form of arsenious acid. A metallic film having been produced, the tube (open at both ends) is held in a slanting position, and the ring is heated; a deposit is produced some distance from the place where the ring was, and which may be either arsenious acid or oxide of antimony. The tube is carefully broken, and one of the pieces brought under a microscope with a magnifying power of 900. If the crystals are regular octohedrons, they are arsenious acid; but if prismatic, oxide of antimony. This oxide never forms octohedral crystals, but only prisms.

On Aroma.—In the course of Chemical investigation, we are often surprised with the emission of odour, while we are unable to account for this peculiarity. An interchange of elements by the decomposition of two inodorous compounds, produces an effect powerfully fragrant and pungent. In the whole range of substances with which we are acquainted, there is not one more capable of eliciting aroma than ammonia. All volatile bodies are of course apt to increase the fragrance of a substance, by carrying the vapour with rapidity to the nasal organs, and diffusing it over a greater amount of surface. Ammonia, however, seems to possess a greater power than is dependent upon mere volatility. To illustrate this, Mr. — gives the following experiment:—I placed in a small still a watery solution of ammonia, and added a solution of essential oil of lemons and nutmegs in spirits of wine. The proportions of oil of lemons and oil of nutmegs were very small; the former being half a drop, and the latter one-eighth of a drop to each pint of fluid. Having adapted the head, I drew carefully over a quantity of spirit corresponding to spirituous solution added, and found it produce a spirit impregnated with ammonia, but of a very fragrant character. Its aromatic power was perceptible as well in its strong state as when reduced with water. The liquid remaining in the still, sent forth very fragrant exhalations, more particularly of the nutmeg. When we consider the minute proportions of aromatic essential oils employed, it certainly appears a case confirmatory of the statement of M. Robiquet, that ammonia lends as it were its volatility to bodies, the odour of which, without such an auxiliary, would be scarcely perceptible. Although the fact of the ammonia being in this case the exciting agent is evident, yet it is singular that after all the ammonial vapour has been driven over, the *caput mortuum* should retain a strong aromatic flavour. The subject of aroma is, however, altogether, involved in comparative obscurity. We know that some proprietary perfumes have gained celebrity, and from what circumstances?—the discovery of a new odoriferous plant or oil? No: but simply because the essential oils are mixed in certain proportions with spirit of wine. Some metals having no odour, emit most powerful exhalations when combined with an inodorous substance. In the manufacture of British Eau de Cologne, it is well known that the addition of a small quantity of the oil of orange flower (Neroli) alters the character of the perfume, and many other cases might be enumerated. Among the investigators of the subject of aroma, we may mention M. Fourcroy, who supposed that odours were merely the effect of simple solution of certain bodies in air. But M. Robiquet is much more conclusive and explicit. He says, when speaking on this subject, "aroma in many instances requires, for its development, the addition of some third body, which, though in itself possessing none of the characteristic odour, yet is absolutely necessary as an intermede, varying in its nature according to that of each odorous substance, as the mordaunt requires to be varied by the dyer, according to the nature of the colouring matter which it is intended to fix upon the cloth." This is certainly a plausible theory, and one which explains many of the singular effects produced by the mixture of substances in reference to smell. But does the addition of the third body, referred to above, not cause an alteration in the particles of the various bodies, thus preventing the organs of taste and smell discovering the predominance of a single ingredient, but receiving all as a new compound? The change is completed instantaneously and frequently, without any appearance of decomposition or chemical action, and sometimes without even difference of colour; can we, then, attribute the changes to a mechanical transposition of the particles of the substances combined, increased or destroyed according to the quantity of some one ingredient, which, when added, seems to usurp an authority, which it exercises by displacing the particles of other bodies, keeping itself concealed, but showing its presence by so far altering the odour of the compound? The subject thus briefly referred to is one of great interest, and may yet attract the notice of some able investigators.

Liquor of Hydriodate of Arsenic and Mercury.—The diseases in which practitioners have hitherto found the liquor of hydriodate of arsenic and mercury to be useful are the various forms of psoriasis, impetigo, porrigo, lepra, venereal eruptions, both papular and scaly, pityriasis, sycosis, ephelis, lupus, sibens, and some uterine diseases. The dose has been variously represented; Dr. Kirby is disinclined to doses exceeding twenty minims, and this quantity, he conceives sufficient to secure its curative effects. In venereal eruptions, Mr. Cusack found ℈i. or ℈ij. three times a day sufficient; but even when larger doses were given he did not observe any unpleasant consequences. It is certainly prudent to begin with Dr. Kirby's dose; but after a while a state of tolerance is induced, and then the medicine may be gradually increased at discretion

Lubanski on the Urine of Pregnant Women.—It is seldom as acid as in other individuals, occasionally it is neutral, and sometimes alkaline, and generally light coloured. Donnè suspected that the salts of lime for the most part are diminished during pregnancy, and that a part of them is taken to supply the materials for the formation of the fœtal bone; and he found in many experiments, instituted for this purpose, that by the addition of thirty parts of hydro chloride of lime to fifty parts of urine, there was a precipitate of from forty to fifty parts of salt of urine in common urine, whereas in that of pregnancy, the most he ever detected was thirty, and very often not near so much. Before making the experiment, the urine to be tried must be tested, to ascertain if it be alkaline or acid; and if acid, a few drops of ammonia must be added to render it alkaline, since the precipitate from phosphate of lime is soluble in weak acids. If the experiment be made with a solution of baryta, there will be in healthy urine a precipitate of from twelve

to fifteen parts of salts of baryta; in the pregnant, from five to eight. After twelve hours' rest, Lubanski found it decisive in three cases of pregnancy, where manual examination and auscultation proved unavailing. He proposes the following questions for investigation:—1. At what period of pregnancy does this diminution of the salts of urine take place? 2. Is it always constant? 3. In what relation does it stand to the increase of fœtal ossification? 4. At what period does it cease? With reference to the question of pregnancy, Donné has, out of thirty-six cases, only *twice* been deceived.

Something Strange.. The *Yorkshireman*, gives the following *morceau* on the authority of an anonymous correspondent writing from Bredlington. Our readers must take it for what it is worth. "Nature certainly occasionally stepped out of her way to produce extraordinary specimens of the human species. We have heard of ladies with four legs, but no arms; women with no hands, and who knit, write, and sew, with their toes; and various other natural curiosities, all of which sink into insignificance when compared with Franceina Kreon, a native of Wyk, by Dunsteede, in the Netherlands, about sixty miles from Rotterdam. She is a female of lady-like manners, and pleasing exterior, about thirty-six years of age. She is from the breast downwards covered with elongated beads, of a dark brown colour, these (incredible as it may appear) indubitably grow out of the skin, and are, to all appearance, as hard as stone; they occasionally shell off, and leave the skin bare for a short time. On their re-appearance they have a setaceous look, resembling a strong beard on the face of a man. All this time the skin is beautifully white, soft, and quite flexible, and may be rubbed double between the fingers. Her knees and elbows are covered with an ossified substance, re- an oyster shell in hardness, colour, and general appearance. Her hands and feet are covered with a kind of shell which, when held before a strong light, is transparent, and has the look of a petrified shell, and is undoubtedly a muscular substance ossified. Many of these peel off towards the end of the autumn, and disappear in the spring; one large piece, resembling a claw, is at the present time about dropping from the left foot. The fingers and toes are separated, and it is only between the latter that the skin is perceptible, and it is quite evident from their appearance that, but for the constant friction, they would be covered similarly to the rest. The bottom of the feet have an incrustation of a whitish horn colour, and is as hard as stone, and transparent as horn itself. There is a genial warmth through the whole frame—this living curiosity has a general run of good health, is of affable and agreeable manners, and takes considerable pains to satisfy the curiosity of her visitors. She is about to visit York and Scarborough, and thence into the north; and will doubtless, become an interesting study for the numerous naturalists, physiologists, and talented medical men with which those places abound."

MEDICAL NEWS.

Mesmeric Operation.—In addition to this extraordinary feat in surgery (Mr. Ward's) we have to add that an operation took place in this parish on the 19th August, when a medical gentleman, to cure a contraction in the knee joint, put a female in a mesmeric trance, and while she was in that state, divided the hamstring muscles without her being conscious of the circumstance; and we are happy to add that the individual now walks with facility.—*Hampshire Telegraph.*

A Medical Consultation in the East.—Whilst I was stationed in Cephalonia, one of the wealthiest merchants of Argostoli a native, was seized with fever, and became so dangerously ill that his life was despaired of. I was requested to see him in consultation. In the ante-room of the patient's bedchamber the family were assembled, the ladies regularly seated as on an occasion of ceremony. Three physicians of the town were present. After examining the sick man, who, strange to say, considered himself then actually dead, and spoke of the folly of prescribing for a dead man, and who, in consequence, after his recovery, was facetiously called by his friends, *il morto*—after inquiring into his present symptoms, we adjourned to the ante-room, and, in the presence of the assembled company, discussed the case; and this was done by the Greek physicians in the most formal manner, each in turn giving a kind of clinical lecture, in which the history of the disease was traced, the rationale of the symptoms given, the supposed exact nature of the malady, and its nosological place assigned, and a mode of treatment proposed, founded on the views taken. It was an ingenious theoretical display of ability, each striving to appear to most advantage; but it need hardly be observed, that it was better adapted to impress an audience with the cleverness of the speakers, than to be of practical use to the patient. In the discussion there was no reserve in the use of terms, on account of female ears: no indelicacies seem to have been imagined by either party.—*Davy's Notes on the Ionian Islands.*

Obituary.—We regret to have to announce the death of Mr. Daniel Cooper, the Editor of the "Microscopic Journal."

Sense of Honour.—We are authorized to announce, that Mr. Erasmus Wilson has thrown up his management of the "The Lancet."

MEETINGS FOR THE ENSUING WEEK.

Dec. 12, Monday,	Medical Society of London, 8 p.m.
	Geographical Society, 8½ p.m.
13, Tuesday,	Roy. Med. and Chir. Society, 8½ p.m.
	Zoological Society, 8½ p.m.
14, Wednesday	Roy. Medico-Botanical Society, 8 p.m.
	Geological Society. 8½ p.m.
	Pharmaceutical Society, 8½ p.m.
15, Thursday,	Royal Society, 8½ p.m.
16, Friday,	Botanical Society, 8 p.m.
17, Saturday,	Westminster Medical Society, 8 p.m.
	Mathematical Society, 8 p.m.

ROYAL COLLEGE OF SURGEONS LONDON.

List of gentlemen admitted members on Friday, December 2nd, 1842:—

J. O'Hea, T. Morgan, D. M. Aitken, J. Dwyre, J. G. Rusher, H. B. L. Brock, T. Bishop, G. Tweddell, C. J. Farr, G. E. Maclaughlin, J. R. King, J. H. Gramshaw.

Just published, price 5s. 8vo. cloth, lettered,

A PRACTICAL TREATISE ON CONSUMPTION—its Pathology, Diagnosis, and Treatment, with remarks on Climate, the Use of the Stethoscope, and a Table of the Physical Signs. By FRANCIS COOK, M.D., Physician to the South General Dispensary.

London: JOHN CHURCHILL, Princes-street, Soho.

BOOKS FOR STUDENTS.

Just Published.

1. A DESCRIPTION OF THE BONES, Their connexion with each other, and with the Muscles. By J. F. South, St. Thomas's Hospital. Illustrated with 250 wood cuts, by Branston, 12mo. price 7s. cloth.

A DICTIONARY OF TERMS USED IN MEDICINE, and the Collateral Sciences. By Richard D. Hoblyn, M.A. Oxon. Price 9s. cloth.

3. THE PRINCIPLES OF THE THEORY AND PRACTICE OF MEDICINE. By Marshall Hall, M.D., F.R.S. 8vo. price 16s. cloth.

4. A BEDSIDE MANUAL OF PHYSICAL DIAGNOSIS. By Charles Cowan, M.D. Second edition, price 3s. 6d. cloth.

5. A PRACTICAL COMPENDIUM OF THE MATERIA MEDICA, for the Diseases of Infancy and Childhood. By Alex. Ure, M.D., A.M. New edition, 18mo. price 5s. 6d. cloth.

London: SHERWOOD, GILBERT & PIPER, 23, Paternoster-row.

MOTHES' CAPSULES OF COPAIBA.

"We, the undersigned, hereby appoint Mr. THOMAS BUTLER, 4, Cheapside, London, our sole Agent (in the place of Mr. Warrick) for the United Kingdom of Great Britain and Ireland, for the sale of 'MOTHES' GELATINOUS CAPSULES OF BALSAM OF COPAIBA,' of which we are sole Proprietors and Inventors."

MOTHES, LAMOROUX & Co.

Paris, Dec. 17, 1841.

T. B. begs to acquaint Chemists, Druggists, and Apothecaries, that, with a view to prevent the substitution of imitations of the genuine Capsules of Copaiba, he will supply the latter at a considerable reduction from the price which has hitherto been charged for them in this country.

MESSRS. WHITTAKER & Co., AVE MARIA LANE, LONDON,

Have just published, price 30s.,

INFUSORIA. The History of Infusoria, living and fossil, with descriptions of all the known species, arranged after Dr. Ehrenberg, and 500 coloured illustrations. By ANDREW PRITCHARD, M.R.I.

MICROSCOPIC ILLUSTRATIONS. A new Edition, enlarged, price 4s. 6d. with descriptions of the Achromatic, Polarizing, and other Microscopes, and ample instructions for use.

This work is the only practical treatise on the USE of Modern Microscopes extant, price 2s. 6d.,

ENGLISH PATENTS, being a Register of all those granted in the *Arts, Manufactures*, CHEMISTRY, *Agriculture*, &c., in 1841, with copious Index, and an account of the new Act to secure designs on articles of manufacture.—Also, Second Edition, price 1s..

A LIST OF 2,000 MICROSCOPIC OBJECTS, with Remarks on the circulation in Animals and Plants seen under the Microscope.

Just published, royal 8vo. bound in cloth, price 9s.

TREATISE on the PRACTICE and PRINCIPLES of HOMŒOPATHY. By Dr. FRANCIS BLACK, M.D. Physician to the Homœopathic Dispensary at Edinburgh.

Homœopathy Explained, and Objections Answered. In 8vo., sewed, price 1s. fourth thousand.

Manual of Veterinary Homœopathy, comprehending the Treatment of the Diseases of Domestic Animals. Translated from the German of M. W. Second edition 18mo., price 4s. bound in cloth.

JAMES LEATH (Successor to Thos. Hurst), 5, St. Paul's Churchyard.

VAN BUTCHELL on FISTULA, &c.—The Sixth Edition.—Just published, in 8vo., cloth boards, price 7s. 6d. (enlarged),

FACTS and OBSERVATIONS relative to a Successful Mode of TREATING PILES, Fistula, Hemorrhoidal Excrescences, Tumours, and Strictures, WITHOUT CUTTING or CONFINEMENT: illustrated with numerous Cases. Being a familiar Exposition of the Practice of S. J. VAN BUTCHELL, Surgeon-Accoucheur.

"It is very rarely our practice to advert to books on professional subjects; but the 'Facts and Observations' appear, by their practical and unpretending character, to indicate so easy and prompt a relief from a large class of most painful and distressing diseases, that we believe this word of commendation from us, which we give with much sincerity, will not be thought misplaced or without its use."—Examiner.

Published by H. RENSHAW, Medical Bookseller, Strand; sold also by the Author, at his residence, 27, Baker-street, Portman-square.

EVENING STAR.

LIBRARY EDITIONS.

The Publisher of the EVENING STAR, grateful for the patronage bestowed on the Double Sheet, containing the Life of Washington, of the 12th of November, 1842, announces that he will issue a standard biographical work every Saturday, in the book form, so that the series may be bound in a volume. The size will be thirty-two pages quarto—the largest sheet allowed by Act of Parliament. It will be stamped, and may be sent free by post. In order to amuse our friends at the Christmas and New Year's Holidays, we shall publish an original novel, entire, illustrated with TWENTY FOUR HUMOROUS ENGRAVINGS. It will be comprised in Two Numbers. The following are the titles of the works which will be published, and the days of publication. December 24th—TOM STAPLETON ABROAD. Part I. With twelve engravings. December 31st—TOM STAPLETON ABROAD. Part II. With twelve engravings. January 7th—THE LIFE AND TREASON OF GENERAL ARNOLD. January 14th—THE LIFE OF BENJAMIN FRANKLIN. These will be followed by other valuable biographies. These editions are totally distinct from the daily Star, and will contain only a synopsis of the news of each week. The EVENING STAR folio, will be published as usual, price 4d. The price of each Library Number of the Library Edition of the EVENING STAR will be SIXPENCE. Orders will be received by every newsman in town and country, or will be sent free, by post, on a remittance of the above amount to the Publisher.

N.B.—Give your orders without delay. Remember every copy is stamped, and may be sent free by post—that entire works are published—that each sheet comprises thirty-two quarto pages—that the series may be bound in a volume for the library, and that the charge is only sixpence a week. Newsmen are supplied on the usual terms.

O. F. PARDON,
Publisher of the Evening Star,

254, Strand, London.

TO MEDICAL MEN. To be Disposed of immediately, a very desirable Medical and Surgical Practice, in a large Town, affording very conspicuous advantages for a well-educated and skilful practitioner. The practice is amongst the first class of patients, and capable of being greatly extended,—consequently none need apply, unless their address and attainments are of a superior order.

Applications, under cover, (P. P.) will be forwarded, and attended to, addressed to Y. Z., care of Mr. Clay, 104, Bold-street, Liverpool.

GEORGE HARRIS, WRITER & LABELLER to the Medical Profession, 15, Little Queen Street, Holborn.—G. H. most respectfully returns his thanks to the Medical Profession, and Chemists and Druggists generally, for the very liberal support he has received as a Labeller and Writer for 20 years, and begs leave to observe, that he now undertakes to fit up Shops and Surgeries in any style of elegance or neatness, and to any price; and trusts, from the great experience he has had with the late Mrs. Willats, Mr. Bruce, and for the last 10 years with the highly respectable firm of Ansell and Hawke, 8, Great Queen-street, Lincoln's-inn-fields, that he will be enabled to give satisfaction.

Stoppered rounds, 1s. per lb., mahogany fronted drawers, 1s. 11d each, labelling in the very best style, 3s. 6d. per dozen. Every article warranted.

CALEDONIAN and CITY of LONDON INFIRMARY, 114, Aldersgate Street, for the definitive Cure of Rupture, &c., so as to enable the patient to leave off all truss wearing, and by timely application, great inconvenience may be avoided. No truss whatever is required. The only thing of the kind in the United Kingdom.—Hours of attendance from 10 to 1 o'clock.

AUCTION ROOMS,

22, Fleet-street.

HENRY SOUTHGATE and Co. beg respectfully to call the attention of their Friends and the Public to their AUCTION ROOMS, adapted for the disposal of Literary Property, Prints, &c. Their extensive connection amongst the cognoscenti of the day, and their favourable situation, the centre of London, and near vicinity to the Temple, and other Inns of Court—render their Rooms peculiarly available for the disposal of Libraries, Large and Small Quantities of Books, Prints, &c.

*** Liberal Accommodations offered on Property intended for Sale.

COALS.—SAMSON and Co., Essex Wharf, Strand, and JARROW, South Shields, Coal-merchants, Importers, &c., assure their Friends that they have unusual facilities for supplying them with COALS, as they are now freighting direct from the Collieries, and would advise early orders previous to the approaching rise in prices. Very best screened, 25s. 6d., seconds, 21s.; Anthracite, for Arnott's Stoves, 29s., within four miles, cash. Founders' and Gas Coke, equally cheap.

WILDENOW'S CAPSULES GELATINEUSES. The partnership between "Wildenow and Grantz" being dissolved, JULIUS KRANTZ begs to state that he continues the manufacture of the Capsules as before and trusts to obtain a continuance of the patronage hitherto bestowed upon the Preparation, to merit which will be his constant endeavour.

J. Krantz cautions his friends against certain persons who falsely pretend to have been in the employ of himself and late Partner, and profess to be able to supply an article of the same superior quality.

10, President-street East, King-square, Goswell-road.

THE THIRD GRAND DISTRIBUTION OF

BIRMINGHAM and SHEFFIELD GOODS, For the Improvement of Home Trade, and giving Employment to our Manufacturers, will positively take place in the large room, Dolly's Chop House and Tavern, Paternoster Row, On WEDNESDAY, 14th DECEMBER, 1842, Commencing at 10 o'Clock in the Morning. This distribution consists of upwards of £1000 worth of Superior Goods, and will be divided amongst 8,000 Subscribers.

Comprising Sheffield Plate, Corner Dishes, Tea and Coffee Pots, Cream Jugs, Sugar Basons, Waiters, Cruet Frames, Toast Racks, Fish Slices, Nut Crackers, Butter Knives, Gravy Spoons, Table Forks, Spoons, &c., sets of superior Ivory Handle Knives and Forks, Bronze and other Table Lamps, Palmer's Patent Candle Lamps, Fine Scissors, Razors, Pen Knives, cases of superior Drilled Eyed Needles, Ladies' Companions, Razor Strops, Silk Purses, Brushes, Warranted London Proved double and single Barrel Percussion Guns, 6 Barrel and other Pistols, Fishing Rods, Walking stick ditto, Fly Rods, Superior Cases of Tackle, Steel and Gilt Goods, Ink Stands, Woods and Son's superior Metallic Pens, Pencil Cases, Ladies' and Gentlemen's handsome Dressing Cases, Writing Desks, Tea Caddies, and Ladies' Work Boxes, Thompson's Domestic Safety Belts, and a variety of other articles, will be divided as follows:—1 share £15 worth, 2 shares £10 worth, 4 shares £5 worth, 8 shares 10s. worth, 150 shares 7s. 6d. worth, 600 shares 5s. worth, 2,500 shares 3s. worth, and the other shares 1s. worth.

Subscribers can select what articles they please to the amount of their shares after their drawing—each subscription 2s. 6d.; receipts can be had by applying at the bar of the Tavern; also at the Depot, 76, Newgate street, where the goods may be seen, and will be ready for delivery on and after Monday the 19th, at 10 o'clock. Parties in the country wishing to subscribe will please to remit 31 Postage Stamps, or a Post Office Order for the amount, and the receipts will be returned by the following post. W. WOODS, Manager, 76, Newgate-street.

BRITANNIA LIFE ASSURANCE COMPANY.

1, Princes-street, Bank, London.

This Institution is empowered by a Special Act of Parliament, (IV Vict. cap. IX.) and is so constituted as to afford the benefits of Life Assurance in their fullest extent to Policy Holders, and to present greater facilities and accommodation than are usually offered by other Companies. The decided superiority of its plan, and its claim to public preference and support, have been proved incontestably, by its extraordinary and unprecedented success.

*** Assurances may either be effected by parties on their own Lives, or by parties interested therein on the Lives of others.

The effect of an Assurance on a person's own life is to create at once a Property in Reversion, which can by no other means be realized. Take, for instance, the case of a person at the age of Thirty, who by the payment of £5. 3s. 4d. to the Britannia Life Assurance Company, can become at once possessed of a bequeathable property, amounting to £1000, subject only to the condition of his continuing the same payment quarterly during the remainder of his life,—a condition which may be fulfilled by the mere saving of EIGHT SHILLINGS weekly in his expenditure. Thus, by the exertion of a very slight degree of economy—such, indeed, as can scarcely be felt as an inconvenience, he may at once realize a capital of £1000, which he can bequeath or dispose of in any way he may think proper.

Detailed Prospectuses, and every requisite information as to the mode of effecting Assurances, may be obtained at the Office.

PETER MORRISON, Resident Director.

A Board of Directors attend daily at 2 o'clock for the dispatch of Business.

SUPERIOR FOOD FOR CHILDREN, INVALIDS, AND OTHERS.—ROBINSON'S PATENT BARLEY, for making Superior Barley Water in ten minutes. Strongly recommended by the Faculty as a cooling and nutritious Food for Infants, much approved for making a Delicious Custard Pudding, and excellent for thickening Broths or Soups.

ROBINSON'S PATENT GROATS form another diet universally esteemed for making a Superior Gruel in ten minutes,—light for supper, and alternately with the Patent Barley is an excellent food for children and invalids, being particularly recommended by the Faculty as the purest and best preparation of the kind extant.

Sold by all respectable Grocers, Druggists, and Oilmen in Town and Country, in Packets of 6d., 1s, and in Family Canisters at 2s., 5s., and 10s. each.

ROBINSON and BELLVILLE, Purveyors to the Queen, 64, Red Lion Street, Holborn, London.

EXEMPLARY INSTITUTE for MATHEMATICS, Engineering, Classics, and General Literature, Surrey Villa, near Lambeth Palace, London.—Principals, OLIVER BYRNE, late Professor of Mathematics, College for Civil Engineers, author of The New and Improved System of Logarithms, The Doctrine of Proportion, A Practical Treatise on Spherical Trigonometry, Proposer of the New Theory of the Earth, which accounts for many Astronomical, Geographical, and Geological Phenomena, &c., and H. W. HULL, B.A. and C.E., assisted by eminent teachers. The objects of this establishment will best be known by perusing the prospectus. Civil engineering forms the leading features in the course of instruction. It will be taught in its most extensive and practical departments, suited to the exercise of the profession. Young gentlemen are also prepared for Oxford, Cambridge, Woolwich, Addiscombe, and Sandhurst. This important course cannot fail, it is presumed, in securing public attention and support. To meet the approbation of the parents of country pupils, and at the same time to facilitate the attendance of young gentlemen residing in London, a situation has been chosen perhaps could not be equalled. References given of the highest order, including noblemen of the highest distinction, whose sons have been instructed by the principals in mathematics, &c., and several scientific and literary gentlemen, all of whom are deeply interested in this laudable design. All particulars shall be given upon application personally, or by letter, post paid, at the Institute, from which prospectuses are promptly sent free to all parts.

H. SILVERLOCK,

MEDICAL PRINTING OFFICE

AND

LABEL WAREHOUSE.

3, WARDROBE-TERRACE, DOCTORS' COMMONS, London.

Where may be had the greatest variety of every description of Labels both Plain and ornamented, for,

Surgeons, Apothecaries, Chemists and Druggists.

*** Engraving and Printing tastefully executed.

ORIGINAL MEDICAL GLASS AND FIXTURE WAREHOUSE.

ANSELL AND HAWKE, of No. 8, Great Queen Street, Lincoln's Inn Fields, begs to inform Gentlemen commencing or altering in the above Profession, that they have a large assortment of Drawers, Bottles, Jars, and every requisite for completing Shops or Surgeries, on the most moderate terms. Most satisfactory references can be given as to style and quality. Plans and Estimates furnished, free of expense.

Valuation of Stock and Fixtures.

PORCELAIN LETTERS.—HUGHES and CLARK, Sole Agents for Yates's Patent Porcelain Projecting Letters and Figures, for Shop Fronts, Hotels, Public Buildings, &c. &c., 158, Strand, (adjoining King's College.) These Letters are recommended with perfect confidence as the most durable, beautiful, and economical ever offered to the public. N.B.—Unglazed Letters for Painting or Gilding.

GREAT COATS, Chesterfield and Brighton Wrappers, Travelling Cloaks, &c.—Families and Gentlemen are solicited to inspect a choice collection of the above GARMENTS in various forms and most approved shapes, made in the first style, from every description of patent waterproof cloths, beavers, &c.—At J. ALBERT'S, tailor, &c., 57, King William-street, City. For prompt payment a saving at least of 25 per cent. may be effected upon garments of the best description.

ENGLISH and SCOTTISH LAW FIRE and LIFE ASSURANCE and LOAN ASSOCIATION.—Established 1839.—Offices, 147, Strand, near Somerset-house and 119, Princes Street, Edinburgh.

The entire Capital of this Association, amounting to One Million sterling, has been subscribed for, upon which Interest at Five per cent. per annum, is regularly paid half yearly.

This Association, by its constitution, embraces—

Every description of Risk contingent upon Life and Fire, on terms as moderate as are consistent with safety.

A liberal system of Loan, whether for a term of months or years,

A union of the English and Scotch systems of Assurance, by the removal of all difficulties experienced by parties in England effecting Insurances with offices peculiarly Scotch, and vice versa;

A large Protecting Capital, relieving the assured from all possible responsibility, and guaranteeing, at the same time, a certainty of the prompt settlement of every Claim; while it also admits every Policy-holder, assured for the whole term of life, to a full periodical participation in Two thirds of the Profits of the Institution.

Individuals possessing real or personal property, officers in the army and navy, clergymen, professional men, merchants, tradesmen, and persons of respectability and character, may, if assured in this office, obtain advances for periods varying from three months to any other specified period, and in amount of £50 and upwards, upon the following securities:

Upon Freehold and Leasehold property in England, and the corresponding description of property in Scotland, either to be assigned or deposited upon equitable mortgage, upon reversion, annuities, pensions, or any other description of assignable property or income, of adequate value.

Upon Personal Security, by the borrower procuring two or more responsible securities, to join him in a bond or other security for repayment, and on condition of the life of one of the obligants being assured.

Upon the security of Policies effected by parties with this Association, according to the value at the time of the loan.

By allowing their Assured to retain a portion of their Premiums at interest.

J. S. PIDGEON, Actuary.

London: Printed and Published by JAMES ANGERSTEIN CARFRAE, 49, Essex Street Strand, in the Parish of St. Clements Danes, Westminster, in the County of Middlesex.—December,10th, 1842.

THE MEDICAL TIMES

A Journal of English and Foreign Medicine and Medical Affairs

No. 169. Vol. VII. LONDON, SATURDAY, DECEMBER 17, 1842. PRICE FOURPENCE. Stamped Edition, 5d.

For the convenience of Subscribers in remote places, the Weekly Numbers are re-issued in Monthly Parts, stitched in a Wrapper, and forwarded with the Magazines.—Orders for the Stamped Edition [10s. 10d. per Half-year, Post-free in advance,] are received by any Bookseller or Newsman, or may be directed to J. A. Carfrae, Esq. at the Medical Times Office, (late Lancet Office), London.

SUMMARY.

COURSE OF LECTURES ON THE DIAGNOSIS, PATHOLOGY AND TREATMENT OF DISEASES OF THE NERVOUS SYSTEM,

By MARSHALL HALL, M.D., F.R.S., Fellow of the Royal College of Physicians, London, &c., &c.

(LECTURE I., Delivered December 2, 1842.)

Gentlemen, it is my office to bring before you the subject of the diseases of the nervous system. In introducing the subject to you, I shall go very rapidly through the anatomy and physiology of that system. I do not think I need go very deeply into the science, because many of you have very probably, listened to the more eloquent words that have fallen on this subject from Mr. Grainger in this theatre.

The nervous system is divided usually into two parts: the first has been called the cerebro-spinal, and the second the ganglionic system. You often hear of the phrase *spinal marrow*, and the question will be for us to discuss what has been meant by that term. I need hardly tell you, that along the spinal canal a chord of nerves runs, which has been very improperly called the spinal marrow. I would venture to call this a chord of cerebral nerves; for it is quite plain that, from any idea of the subject that we have formed, it is neither more nor less than a chord of nerves proceeding from the cerebrum, and passing along the spinal canal, and out of that into the different members of the body. We will, therefore, view it a few moments as it ought to be viewed, as a mere chord of spinal nerves running along the spinal canal. But there is another view to be taken of the subject, for you have, no doubt, studied the *ganglionic* system. Now the ganglionic system is traceable through its nerves, also to the spinal canal—at any rate it is traceable to the spinal nerves, and, therefore, the spinal chord may be viewed also as the source of the ganglionic system. Farther than this we have not proceeded. Until very recently we viewed the contents of the spinal canal as a chord of central nerves, and the origin of a part of the ganglionic system. Now, gentlemen, it is very possible to remove the *cerebrum*, the centre of those nerves, and the *ganglionic* system, and yet leave *another kind* of nervous system remaining in the animal body. I shall take this early opportunity of showing you a simple experiment. You see here an animal (a frog), from which the head has been separated, and, of course, I need not tell you, that with the head the brain has been entirely removed; all the viscera have also been removed, and with the viscera every portion of the ganglionic system. Now, I beg leave to repeat,—the cerebrum, the centre of the spinal chord of nerves, and all the ganglionic, have been removed from this animal, and yet when I pinch the extremity, it moves, so as to be obviously perceptible at the remotest part of this theatre. Thus, as I said before, we have here removed the centre of the cerebral system, and the entire ganglionic system. The brain, which we know to be the centre of all the sentient and voluntary nerves has been removed, the ganglionic system has been removed, and yet you observe something remains. Now, gentlemen, that which remains I venture to call in contradistinction from what has been termed a chord of cerebral nerves, and the origin of the ganglionic system—the *true spinal marrow*. It is plain, in the first place, that it is not a mere chord of nerves; if it were a mere chord of nerves, you might divide it, and then you would intercept its influence. But, if you observe, here, this influence passes not only from one extremity to the other, but it also passes from the one *set* of extremities to the other set of extremities; thus, it is quite plain that there is a nucleus of nervous matter between the two anterior extremities, and another nucleus between the two posterior extremities, by which these various limbs are united and associated in their motions one with another. Having thus, then, clearly laid before you the distinction which I wish to insist upon; namely, that there is not a division of the nervous system into *two* parts only, but into *three*, pervading all the different parts of the whole animal frame, I shall venture to term them, the cerebral, the true spinal, and the ganglionic systems.

The cerebral system has the brain as its centre. It consists of sentient nerves, which proceed from the ultimate parts of the animal frame to the brain, and other nerves which go to the muscles, and which may be termed voluntary. Nerves, therefore, which convey sensation, and nerves which convey volition may be called the system of sensation and volition, and I need hardly tell you that between sensation and volition you always see an intellectual operation. There is between all these nerves an organ, the cerebrum, for intellectual operation. The cerebral system, then, is the system of sensation, intellectual operations, and of volition and voluntary motions.

Now, I am about to mention a fact to you, which is exceedingly interesting, because of its important application to pathology, and, therefore, to practice. But first of all, I must mention, that the principle which acts in the brain is the immortal soul. With regard to the substance of the brain itself, what I wish to insist on is, that it possesses no power of sensation, and no power of exciting motion; that is, if you take an animal, and lay the brain perfectly bare, and lacerate the brain in every possible way you can devise, you cannot in any manner induce pain or sensation—you cannot in any manner induce muscular motion. This point is so important that I beg leave to repeat it; and, indeed, I may mention a circumstance which will enable any of you at any time without inflicting the slightest suffering to convince yourselves of this fact. Perhaps not many of you have seen the mode in which horses are killed. The usual mode is to take a pole-axe, and strike the horse on the cerebrum, and it falls down instantly. But the horse is not dead; it is not altogether dead to sensation, because most of the brain is entire, and there is a certain portion of that organ which is the organ of sensation. If you take a small instrument, or a cane, and pass it through the circular orifice made, and lacerate and injure the brain surrounding the orifice within, in any way you think proper, you will not induce the slightest pain, neither will you induce the slightest muscular motion. Therefore, it may be said, that the organ, which is the central organ of sensation, is insensible; that that organ which appeared to be the organ of certain motions, is incapable of exciting motions. This I should mention is one circumstance, which, to my mind, shows that intellectual and sensitive functions are not the functions of mere organized matter. I take it then for granted, that this mass of cerebrum is insensible and incapable in itself of exciting any muscular motion.

Now with regard to the pathology of the brain, I mean rather to the functional pathology of the cerebral system, I need only tell you it consists of modifications of sensible and of intellectual power and of modifications of voluntary acts. So that where you find morbid sensibilities, and morbid developments of intellectual faculties, and morbid developments of voluntary motions, you may take it for granted, that the brain, as the centre of all the cerebral system is affected. With regard to the therapeutics which may be said to have their operation through the cerebral system, I need scarcely say a word. It must consist in what has been called the moral treatment.

Now, Gentlemen, I pass on to the other system—*the true spinal system*, and I do it the more readily because I am more than ever anxious to show you how a knowledge of this system is absolutely essential to you, entering on the practice of physic; and the treatment of diseases of the nervous system particularly,—how important it is in diagnosis and prognosis, and how important it is altogether in practice. The central part of the true spinal system is within the spinal canal; I venture to call it in contradistinction to the spinal chord of cerebral nerves, the centre of the ganglionic system, the *true spinal marrow*. It is the cerebral organ of a number of phenomena and a number of actions, and a number of functions; one or more of these I will show you; indeed I have already shown it in this animal (the frog) which you see to be perfectly alive in that sense of the word. It lives, as it were, a true spinal life; it is neither sensible nor is there any spontaneous or voluntary motion. The organ of sensibility, and, therefore, of voluntary motion, is taken away. There is no ganglionic system, and nothing is left but the true spinal system; the true spinal marrow; the nerves that run into it, and the nerves that run out of it. The first characteristic of this system is, that it is carried on through the medium of incident and reflex nerves. For, what takes place when you inflict a wound on the toe? Of course, it is quite certain that the impression induced, produces some change, running along the nerves, and these carry it to the spinal marrow, by which it is reflected back again to the muscles, and so it is that the limbs are caused to move. You see, therefore, that the anatomy is characterised by one special word; it is *incident* and *reflex*. The incident nerves run up to the spinal marrow, the reflex nerves run from that organ, and whenever we produce a motion, we produce it through the medium of this system; we produce it through the medium of this peculiar anatomy. It passes from the point intimated, up to the spinal marrow and thence down to the muscles. So the operation is altogether reflex, at least, there are only one or two exceptions in the animal frame to this very general rule.

The next point to which I wish to draw your attention is the peculiar property, faculty, or function of this spinal marrow. A very short time ago I said, lacerate the cerebrum as you may, you cannot produce either sensation or motion, but the moment you make an experiment, and touch the true spinal marrow, then the whole muscular frame is thrown into violent convulsions. The true spinal marrow then is *excito-motor*. The brain is *in-excitor*. This power was described by Haller as the *vis nervosa*, because it exists not only in the spinal marrow, but also in the different nerves going from it. If the nerve is irritated, the muscle to which it is distributed, is thrown into contraction. If instead of irritating the nerve, you irritate the spinal marrow, you produce contraction in all the muscles which receive their nerves from below the part irritated. Haller and Müller, and all the authorities, have said hitherto that this *vis nervosa* acts in one direction only; that is, from the centre towards

the circumference, from the spinal marrow towards the muscle to which the nerve goes; but by recent experiments, it has been determined that this is not true, in fact, that another law besides this, which may be considered the *direct* law, obtains with regard to this peculiar function. If in the lower order of animals, if in the cold blooded animals, you irritate the spinal marrow, the muscles, the nerves of which take their origin *below* that point will be called into action, but a number of muscles that receive their nerves from *above* the parts irritated are also called into action. In this case the influence presents both a direct and retrograde action,and the same power acts upwards, and to the right and to the left, to the superior extremities, and to the inferior extremities. In the former direction its agency is not so energetic as in the latter. If you irritate one of the cutaneous nerves coming from the skin, if in the cold-blooded animals, you have still the same action as before. What must have taken place? The energy of the *vis nervosa* must have been excited, and an influence sent in an incident direction, then in an upward or retrograde direction, as well as downwards, to both sets of extremities. It acts first of all in an incident direction, then upwards, then downwards, and lastly into both sets of extremities. It is exceedingly important to notice this with various objects; in the first place to correct the erroneous view which has been laid down by the physiologists I have mentioned, and others, that this power acted only in one direction, that is *from* the spinal marrow *to* the extremities of the nerves; and secondly, to set forth this new law, viz., that it acts in the opposite direction, in a retrograde manner as well as to the extremities, and lastly, in an incident direction, which may be called retrograde with regard to the nerve.

We have now a very clear view of the mode of operation of this *excito-motor* function — these incident and reflex nerves — this reflex action. Now the question comes to be, whether we have any applications of this function? whether this function be created in vain? or whether there be a set of phenomena and functions connected with this source of function—this *motor* power? Gentlemen, it would be very extraordinary if the power did exist, and therefore were created, without an end or without a design. But there *is* a vast design here; for there is precisely a parallel series of functions to be performed through the medium of this *excito-motor* principle. Before referring to these functions, I will first of all give you a list of them: in the first place, there are the orifices into the body—these are guarded by that function; in the second place, there is ingestion, and, for instance, inspiration and deglutition—these are all conducted under the influence of this power; then there are the acts of expulsion, the expulsion of the fæces and the semen—all these expulsions are conducted in various degrees under the influence of this power; and, lastly, there are certain organs that prevent certain materials that ought to be retained in the body, from being expelled from the body — all the sphincters are under the immediate influence of this power.

When I go over the subject anew, as I do at this moment, just talking to you as I would to my intimate friends in common conversation, I do confess the subject strikes me with a little wonder at its extent and magnitude.

I say, then, that ingestion and expulsion depend on this *excito-motor* power. Formerly, we knew one part of the nervous function exteriorly to be, that of the cerebral system—destined for the observation of external nature—to obtain a mental knowledge of the objects seen around us. This is the function of our mental relation with external things. There is another function formerly well known; that is, substances which are taken into the interior animal frame, are diffused so as to nourish all parts, to be taken up, and carried away from the system by other organs, and so on. This, of course I need not say, is performed by the ganglionic system. The cerebral system, by which we have relation with the external world, is well known; the ganglionic system, which makes use of every thing taken into the interior, also is very well known. But I believe it was never determined by what power certain substances are taken into the interior of the animal frame, to be so made use of, and other substances rejected from it. To say one word respecting the most considerable, the most important, and the most extensive of these functions—*respiration.* We breathe for ever; from the beginning of man to the close of life, we do not cease to breathe. This act of breathing is entirely under the influence of this *excito-motor* power. From the moment the fœtus is born —the moment it passes from a warm medium into a cold medium—the moment this takes place, the whole surface of the body is convulsed by the cold medium, and immediately, through the medium of this *excito-motor* system, inspiration is excited, as under the influence of cold water. On going into a cold bath it is totally impossible to suppress sudden acts of inspiration, which are called into action in a moment.

Here, then, we have one of those phenomena never explained until the *excito-motor* system was explained by myself. In fact, I may say, former physiologists were obviously wrong on this point, who, including Müller, and after him Sir Charles Bell, supposed the medulla oblongata as the exciting cause of acts of respiration. Now the medulla oblongata is not the exciting cause of any acts of respiration; in fact, every act of inspiration is caused by and through the nerves going from the exterior to the interior, through every joint of the body to the medulla oblongata, through the medium of the excito-motor power, as the source from which the nerves that pass through the system receive their excitement. One very interesting point appears to me, that so far from the medulla oblongata being an excitor of inspiration, it is not the excitor of any physiological effort; but it is the excitor power under certain circumstances of *pathological* acts. For instance, in the state of *asphyxia*, which takes place when you put an animal under cold water, what are the phenomena of *asphyxia*? They have been all confounded with the act of respiration, and with the lungs by the act of expiration. If you induce asphyxia in an animal under water in a temperature of 98 deg., I beg you to observe, that it is quite astonishing how soon the struggles end. It is quite astonishing how soon the brain is poisoned,and insensibility induced by the circulation of undeglutinized matter. These struggles cease almost in an instant, and then what takes place? It has been said that attempts at inspiration take place. Gentlemen, this is not the fact; and I have continually and repeatedly assured you, and so have others in this room, that respiratory efforts are not efforts of inspiration, but expiration. Take a young frog, and you observe the system is thrown into a state of exhaustion; the stomach is compressed as well as the lungs, and a vomiting is produced by this apparent act of expiration; the act is not only one of expiration, but it is produced by the power of undeglutinized blood on the central part of the spinal system. Here we have action obtained by that mode; here is the *primum mobile*, and here it ceases to be a physiological act, and becomes a *pathological* act; and it is quite extraordinary how important the diagnosis comes to be. I will illustrate the subject by another example which I think will strike you all. Have we not in all works on pathology, universally seen that *tetanus* and *hydrophobia* are linked together, as being diseases of the same character, and produced in the same manner; and, in fact, having the same pathology? Gentlemen, it is so far from being the case, that uniformly *tetanus* is a reflex action excited through the medium of incident nerves, which produce their effect on the spinal marrow which spreads the action over the whole muscular system. Whereas, in *hydrophobia*, the blood is poisoned, and the blood acts on the spinal marrow: as in the one case you have incident or reflected action, in the other you have the spinal action. In the one the action is produced by the medium of the incident nerves, and the other action is produced through the medium of the blood on the spinal marrow, carrying its poison through the cerebral system, and thence to themselves and nerves, and is reflected, and so every muscle is affected in this case. Then, I have said, I would only illustrate the subject by one case; but there is another fact so very important, that I must mention it. It has long been a question with some, how morbid agents act on the animal frame? How do poisons act? You find in all works they have been divided between the vascular system and the nervous system, and some have been so unphilosophical as to suppose, that poisons act both ways; both through the medium of the nervous system, and through the medium of the vascular system. I can tell you in one word,what acts through one medium and what through the other. If you inflict a violent burn, the action is external, and corrosive poison acts internally; they act through the medium of the nervous system. All poisons that act slowly, you will observe, act through the medium of the vascular system. The subject is, therefore, well worthy of consideration. You observe it has a most immediate application to pathology, diagnosis, and to practice.

Here I will just leave the subject of this *excito-motor* system, because, as you are perfectly aware, this course of lectures is not on the nerves, but on the treatment of diseases of the nerves. Before I leave it, however, I want to impress on your minds one point, about which I am exceedingly anxious. I have stated already one broad fact to convince you that a knowledge of these various actions of the nervous system is absolutely necessary in practice, in diagnosis and prognosis.

Now I will suppose a case of disease of the brain. Gentlemen:—A disease of the brain cannot—*quasi* a disease of the brain—produce one muscular action. As I said before, disease of the brain cannot, as a disease of the brain, produce a muscular action. It may be acted upon so as to produce morbid indications, but it cannot produce spasmodic actions. Why cannot it do it? Because it does not possess the power. I have already stated the brain to be insensible. The brain is not capable, lacerate it as you will, of inducing any spasmodic or convulsive action of itself. Suppose then, in disease of the brain you have at the same time spasmodic action, what is the conclusion to which you must come? You must come to this conclusion. Diseased as the brain may be, it is not confined to the brain; it must inevitably extend beyond the brain, some other part must be affected. If the disease of the brain is not removed, it will extend to some other part entered by the *vis nervosa*. Here you have at once the diagnosis of diseases confined to the brain, also of diseases attacking the brain, and also of their extension to other parts of the system.

There is another view of this subject, which is not only worthy of your attention, but worthy of your attention as practitioners, as I suppose you will assuredly become. I am exceedingly anxious to impress on your minds this important fact, that it is the study not merely of anatomy, not merely of physiology—and not one of you can become a practitioner without being a physiologist—but it has its immediate application to the practice of physic. It has been truly said by some professor, a very amiable man, a short time ago, that it is often the fashion to walk the wards of the hospitals without being able in many morbid cases that occur, to determine the *excito-motor* phenomena of various diseases of the nervous system.

One word more on this subject. I have hitherto spoken a few words on physiology and a few words on pathology. I will just add a few words on another branch connected with it, namely, *therapeutics*, and in a very especial manner *therapeutics* is connected with the subject I have been laying before you. Why? It would be very extraordinary if there were this power in the human or animal frame, and it had not this application to pathology, but also to the treatment of diseases. There is one agent acting through the medium of this system of nervous influence, and that is in the sudden immersion in cold water. What would you do in a case of child-birth in a state of asphyxia? The first and important remedy after an immersion of the child, is to throw cold water on the face, and excite inspiration, as in the case of common asphyxia. In drowning, the same remedy may be applied. There are a thousand other cases in which you can use the cold water. I have a very interesting letter from the country this very day, written by a gentleman now residing at Stamford, a gentleman to whom I am indebted for the beautiful illustrations in my work on the nervous system,

published a year ago,—Mr. Simpson. He says, alluding to a very interesting case of convulsions, the patient was roused from a state of stupor to a state of consciousness. She had an extraordinary degree of obstinacy; she would not swallow anything. I put the instrument in her mouth, but she would not swallow any food. I threw cold water on her face, and she swallowed it immediately. In this manner I fed her, and repeated the experiment from time to time. But this was not all, for the child was not born. Every attempt to excite the uterine system to contraction failed. My friend laid bare the uterine region, and applied the douche of cold water to the surface. Instantly the uterus was called into action. This was repeated until at last the skin of the abdomen became cold. Of course the cold water on the surface could not produce it. The child was born, and the woman was saved. Here then you have a distinct application of the *excito-motor* system to practise, and there are many others I shall have to mention to you in their turn when I come to discuss the various diseases. I will only mention one more in concluding this subject. I need hardly tell you that there arises a sort of sickness in all nervous movements, which is always produced by irritating the nostrils, and causing what sometimes takes place in action of a morbid kind, and of a convulsive character. Sometimes we wish, as in cases of poison, to excite vomiting. Before you can get a remedy, or an emetic is prepared, or the stomach pump is brought in, before you do anything, you can irritate the nerves, which will produce the desired effect. I tell you this that the irritation of the fauces which close the larynx, and the organs of respiration, and forcible pressure being applied to the abdomen, vomiting may be produced. Is not this important to know, in the possibility of such an emergency as that of a patient having swallowed a dose of laudanum unintentionally, or any other poison! There is another fact I will yet mention in conclusion. We know that *cantharides* have an effect on the neck of the bladder, and we also know their effect on the uterine system. We also need know how this remedy acts with reference to the excito-motor system. On this point I may mention the case of a patient who had taken that substance in excess. I mention it in order to know what is the effect produced by cantharides.

It produces a state of things precisely like epilepsy or strangulation. The patient seemed as if she should be strangled, and nothing would relieve her but throwing cold water on her face—in fact, to convulse the larynx.

I have said enough to convince you, I believe, that we have very much to learn in use and practice by pursuing this subject of the excito-motor system. This lecture is not a lecture on the excito-motor system, but it is on the subject of diseases of the nervous system generally, and I will take care that I will not occupy you too much with a subject that may be considered a favorite one of my own, with the study of the diseases of the cerebrum and the spinal marrow. All that we know of the diseases of the spinal marrow—all that we know of the diseases of the ganglionic system—what is it that we do know? Next to nothing. All we do know is a little of the anatomy and physiology, and a little of the pathology. Perhaps one of the most important parts of the pathology of the nervous system, is the peculiar effect produced on it by the motions of the *excito-motor* power.

I will mention a fact or two, in conclusion, to convince you. Take a frog, at a certain season of the year, and by slow degrees remove the brain, a part of the brain and spinal marrow, then another part of it, and then the whole of it, acting by degrees, and leaving an interval of an hour between the operations, then remove the whole brain and the whole spinal marrow, leaving the ganglionic system alone, but entire. Then you have left the perfect action of the heart, and you have the perfect circulation of the blood, and the perfect action of the lungs. Now, then, if with an animal so prepared—so destitute of every part of the nervous system except the ganglionic—if you just take a hammer and crush one of the limbs, you immediately arre t the act on of the hea t. But the act on goes on afterwards, palpitating, though not as before, because the circulation is never restored; therefore the ganglionic system has received an impression which immediately produces its effect on the heart, which can no longer carry on its offices as before. An accident will do the same thing. I will mention but two cases, and then I will leave the subject, having already, perhaps, exceeded my hour. You remember the case of the late Mr. Huskisson, the first victim to the discovery of the railroad. It was when the Liverpool and Manchester railroad was opened; he was addressing some conversation to the Duke of Wellington, when he received an intimation of the train approaching; he was absent, or had not presence of mind for the moment, and he was run over by that dreadful vehicle. You all know the consequence. His leg was crushed, and the heart immediately received an impression. The surgeon waited very properly for reaction; reaction never took place, and amputation never could be performed. Here you have an action produced through the medium of the nervous system, upon the heart, the consequence of which was to exhaust its power and prevent its carrying on the function, so necessary for life, as circulation. One fact more. You know the history of General M——. Both limbs were wounded, and one was amputated, when the surgeon said, "I am sorry to say I must amputate the other." The general, with all the bravery of his nature, said, "Proceed with your work, gentlemen;" he sunk under the second operation. He did not recover from the second infliction of violence—physical violence—inflicted on the ganglionic system which the second operation brought about. Here then you have a double fact. In the first place, if we wish to amputate a second limb, what should we do? We should wait until the impression made by the first was entirely removed. We have also this fact, that the impression is made expressly through the medium of the ganglionic system. I am anxious to give the whole view of the subject in the short space of a few words, and on Monday we shall proceed further into the subject.

ON THE LAWS OF THE DEVELOPMENT OF ORGANS; OR, TRANSCENDENTAL ANATOMY APPLIED TO PHYSIOLOGY.

By E. R. A. SERRES, Member of the Institute, of the Academy of Medicine, Professor to the Museum of Natural History, Paris, &c., &c., &c.

SUMMARY.—*Reproduction of human embryogeny in the organisation of animals—The tail as existing in the embryo of man from the fifth to the seventh week—The optic lobes; their mode of development—The cerebral hemispheres—The cicatricula an independent being—The blastodermic membrane—The digestive tube; its early formation—Relation of organogeny with zoogeny—Zoonites—Differences and analogies between organites and zoonites, with regard to their mode of existence, and the various forms under which they become associated.*

In my last lecture I have shown you that human embryogeny is merely a repetition of comparative anatomy; we shall now, however, find that human embryogeny is itself reproduced, in some points, in the organization of animals. What is there more remarkable than that singular tail-like prolongation presented by the human embryo from the fifth to the sixth and seventh week? If any character of a prominent nature distinguishes man from the mammifera and *quadrimani*, it is assuredly the absence of the tail. In the embryo, however, we find that this appendage does exist, an outward sign of the resemblances binding man with the chain of beings of which he constitutes the head. A further peculiarity presented by this characteristic is, that it is at the period of its manifestation, or during its duration, that the organic repetitions of comparative anatomy are reproduced. Thus, it is at this period that the penis, the clitoris, the prostates, the womb, &c., of the embryo, are counterparts of these organs in certain adult animals; it is at this period that the fractional state of the cranial and facial bones in the embryo represents the permanent or normal condition of these parts in the mammifera, reptiles and fishes. It is also at this period that the liver, the kidneys, the intestines, and the heart, are transiently clothed with the forms of these organs in the lower animals, and that the human brain is disguised under the characters belonging to fishes, to reptiles, and to birds. Lastly, we may state, that this tail-like prolongation has merely an ephemeral existence, like all the other organic resemblances of the embryo; it disappears in the course of the third month; and it is from this period that man, leaving behind him all other organized beings, advances by large strides towards the type of organization presented by him in after life. This change is especially interesting in reference to the series of metamorphoses which the brain undergoes in the embryos of the superior mammifera. Having ascertained the primitive analogy of its elements through all classes, it becomes necessary and indispensable to explain its dissimilitudes in adult animals, for these elements changing in form and position, and undergoing in each class new transformations, the whole brain is so far modified, that that of one class is not distinguishable from that of another, a fact which has hitherto prevented our perfectly understanding its nature, and which ever would, if we persisted in confining ourselves to its consideration solely on its permanent phases, and only *after* it has undergone these extraordinary phases.

To prevent our being misled by these continual changes, we must follow step by step each of these metamorphoses through all classes; and by taking into account the influence which the evolutions of one element exercise over the others, we shall be enabled to trace the brain through all its transient forms, until it reaches its permanent or normal condition. Such is the course which I propose to follow in the elucidation of this subject. Let us take either the tubercula quadrigemina, or the optic thalami in the three lower classes:—In all embryos these bodies are lobular, double and hollow; they occupy in all classes the superior surface of the brain, bounded behind by the cerebellum, and in front by the cerebral hemispheres. In their various evolutions these primitive relations alter considerably. In reptiles and fishes these bodies preserve the same form, the same position and relations. Not so, however, with birds and the mammifera. In birds they remain, as in reptiles, upon the superior surface of the brain, up to the middle of incubation. At this period they abandon this position, becoming gradually projected towards the sides of the peduncoli of the pineal gland, and finally occupy the base and sides of the brain, where they are met with in all perfect birds. They, however, preserve, as in reptiles and fishes, their internal cavity. In the mammifera alone this cavity is obliterated, and these bodies become solid, like the spinal marrow. This solidification takes place, as in the last named part, by the deposition of concentrical layers. Originally these bodies are lobular, double and hollow, as in the three lower classes, and they preserve this form up to about two-thirds of the period of gestation in the animals composing this class. At this period, which corresponds to the epoch when their cavity becomes obliterated, we see appear upon their surface a transverse groove which divides each tubercle into two. These two lobes are converted by this groove into four distinct tubercles, hence receiving the name of corpora quadrigemina. If in birds the optic lobes become arrested in their progress, they preserve the same place in which we observe them among reptiles and fishes. If in the mammifera the transverse groove does not manifest itself, these tubercles remain oval, hollow, and merely divided into two, as in the three lower classes.

Secondary differences arise in birds from this displacement of their optic lobes. In fish, reptiles, and mammifera, these bodies remain in their primitive place; the transverse layer which unites them above, experiences no modification. In birds, however, the case is different: in proportion as the lobes are separated one from another, their surface unfolds itself, the median layer which unites them extends itself, so that in adult birds, we find in the place which they occupied at first, and which they preserve in other classes, a large radiated commissure, composed of alternate series of white and grey matter. Such are the outer modifications shown by these bodies in the four classes. But however great the differences presented by the four

solid tubercles in the mammifera compared to the two hollow lobes in reptiles and fishes, whatever change in position may be experienced by these parts in birds, we see that it is always the same organ, disguised only by these different metamorphoses. Let us now consider the cerebellum. As soon as the two transverse layers forming it are united with the structure composing the valve of Vieussens, this organ is formed in all classes by a small oval portion, constituting an arch above the fourth ventricle. If the cerebellum is arrested at this period of its development, it preserves in animals its simple and elementary form. This is the case in all reptiles and the greater number of bony fishes. But, suppose that before the union of the transverse layers, the medulla oblongata becomes greatly enlarged, and that these layers do not increase in the same proportion, what then occurs? We see that the union of these layers does not take place upon the median line; they become folded one upon the other without uniting; the medullary layer of Vieussens remains floating upon the fourth ventricle, which it partly covers. This is the case with certain cartilaginous fish. Fish and reptiles then preserve the embryonic forms of the cerebellum, and permanently resemble, in this respect, the embryos of the superior classes. In the latter, the cerebellum acquires considerable dimensions, its surface is grooved with more or less numerous transverse lines of variable depth; at the same time it forms upon the sides and top of the brain a more or less marked projection. But these dissimilitudes produce no change in its tendency; it is still the same organ reduced in the two lower classes to its minimum of development, and carried to its maximum in the two upper classes.

It, however, appears more difficult to bring the cerebral hemispheres of fishes to a level with those of the mammifera: for we see on the one hand organs of great simplicity, and on the other organs exceedingly complicated, having no manifest relation with the first, either in form, configuration or structure; all those characters which serve anatomists to recognise the *homogeneity* of organs being absent, one would be tempted to believe that these parts were altogether dissimilar, and had no analogy one with another. But on tracing upwards the uterine life of the mammifera, we at first perceive the cerebral hemispheres rolled up, as in fish, into two vesicles isolated one from another; afterwards, we see them assume the configuration of the cerebral hemispheres of reptiles; later still, they present the form of those in birds; and, lastly, they acquire only at the period of birth, and sometimes even later, the permanent forms presented by the adult mammifera. The cerebral hemispheres arrive then at the state observed in the superior animals only by a successive series of metamorphoses. If it were possible to develop the various parts of the brain in the lower classes, we should successively make of a fish a reptile, of a reptile a bird, and of a bird a mammiferous animal. By atrophying, on the contrary, this organ in the mammifera, we should necessively reduce it to the encephalic conditions of birds, reptiles, and fish. Nature, in some cases of monstrosity presents this latter anomaly; but never have observers noticed instances of the former. In the numerous irregularities experienced by organised beings, we never find them surpass the bounds of their own class to assume the forms of a superior one, never do we find a fish assume the encephalic forms of a reptile, the latter those of birds, or birds the development of the mammifera. A monster may present a repetition of its various parts; it may have two heads, two tails, six or eight extremities, but it always remains strictly confined within the limits of its class. This phenomenon is undoubtedly characteristic of the general harmony of the creation.

We thus perceive that the differences of the brain in the various classes are principally composed of metamorphoses; that its dissimilitudes are established upon one common basis; that the fundamental organ remains the same in all. We thus see that if these evolutions become arrested in an animal during the course of its transformations, such animal must necessarily present the organic forms of the class at which it is arrested. But the essence of animality resides neither in the vessels and the heart, nor in the brain and its dependencies, nor in the genito-urinary system; a being may exist and live without the presence of these organisms. Not so, however, with the nutritive apparatus: life can be maintained only by the absorption of assimilative molecules; it is this property alone that endows an organism with its capability of life. Hence it follows, that in descending the animal kingdom, we see beings at the bottom of the scale reduced to an absorbing vesicle, and, on mounting to the highest possible point of embryogeny, we also find the rudiments of the embryo constituted by a similar vesicle. Animality and life commence in both cases by a similar organic apparatus, reduced in its assimilative properties to the most simple conditions possible. Thus the *monada*, among the infusoria, are represented in embryogeny by the proliferous vesicle recently discovered by M. Purkinje. The *volvoces*, &c., are reproduced in the early embryonic state by the *cicatricula* of the ovum; for the *cicatricula* is already a being having a peculiar kind of existence, similar to the conditions of vitality among the lower infusoria, and the development of the *cicatricula*, and that of the embryo, the elements of which it contains, are the result or product of its life. Thus, in comparing the development of the *cicatricula* of the chicken, with that of the lower animals and the infusoria, we see that the first rudiments of the mucous layer of the blastodermic membrane are represented by the mucous membrane of the *volvoces* and *proteus*, that the intestinal folds of Wolf, which correspond to the primitive duality of the intestine of the chicken, are, perhaps the true state of intestinal duality in several species of *vorticellæ* and in the embryo of the *anodonta*.

To this primary state of the digestive canal of the chicken, succeeds a second not less remarkable; this consists in its division into three parts,—a median, the most imperfect, although central, and two peripheral, or external portions; a mode of formation represented by the embryo of the lobster, in which M. Rathke has seen the isolated development of the gastric and of the intestinal portions. Again, is not this imperfect state of the alimentary tube a reproduction of the permanent condition of the intestinal canal in the vermicular *animalcula*? Is not the invagination of the double digestive canal of the earth-worm, the *balanus*, &c. a permanent representation of the mode of formation in the embryo of the lobster? We thus perceive that whatever imperfection may exist in the first rudiments of the intestinal canal in the embryo of the vertebrata, we shall find its counterpart in the permanent organization of the inferior animals.

The lower animals also reproduce in a very evident manner the following metamorphosis of the embryonic intestine of the bird. We know that when the three parts of the digestive canal become united, this canal is straight and merely of the length of the young embryo; now, such is the case with most of the zoophytes. We know also that at the period of this union, its two extremities are closed, that it is a double cœcum; now this double cœcum is an exact repetition of the second alimentary tube, affixed in the ordinary intestine of the earth worm—an arrangement to which M. Ch. Morren has given the name of *typhlosole*. Such is also the case with the greater number of *vibrions*, *cyclides*, and some of the *tricodes* among the infusoria. We know again that the double cœcum of the embryo opens at first by its anterior part, so that if its nutrition, as some physiologists still think, is partly accomplished by the intestinal canal, the same opening serves the purpose both of mouth and anus; now, we are all aware that this imperfect arrangement of the alimentary canal is precisely that of the greater number of zoophytes, especially of the *pennatula*, the *renilla*, the *alcyonea*, &c.; also of several species of the *tricodes*, among the infusoria. We know, finally, that at a more advanced period of embryogeny, the intestine is open at both extremities; that there then exists an anus distinct from the mouth.

That is the permanent condition assumed by the alimentary canal in the lower animals, presented to us in a transient manner during the embryogeny of the vertebrata. The one condition is the reproduction or the repetition of the other. Organogeny is, then, but a transient comparative anatomy, and comparative anatomy a permanent embryogeny. Numerous examples may be found of this concordance of human organogeny and comparative anatomy. We see in the beginning the isolated state of the organisms in the human embryo, as well as in animals, together with the ultimate association of these elements; so that these organic elements being invariably given, nature associates them to their highest degree in the development of man, and maintains them disassociated in various degrees in the development of animals. From this association and disassociation result organic forms; the form of the organs is then merely a secondary condition, and its variations are as numerous as the combinations of the elements producing them. The globular, cylindrical, spherical, or demi-spherical forms, are those towards which the *organites* tend in their associations; whence it follows reciprocally that from their disassociation results the decomposition of the globular, spherical, or demi-spherical form of the organs which they constitute by their union. Now, in human embryogeny, organogeny is directed towards raising the organs to this high point of association; it therefore follows that the higher we proceed in embryonic life, or the nearer we advance towards the original condition of the organs, the more will the organisms be found to be disassociated or isolated. Such, also, is the case in comparative anatomy. There are, however, some differences between these two branches. In the human embryo, the organisms during their development traverse quickly through their primitive forms; they glide rapidly through them to arrive at their proper and harmonious condition. The definitive result of this development is then to associate the organs, and to combine their elements so as to form a compact group of the various parts which the young embryo presents at its commencement. In animals, the same tendency to unity of the organisms is manifested throughout the whole animal series and in each of the organs constituting them; but it fails either entirely or in part. The effect of this failure is then the disassociation of the materials constituting the organisms. It therefore follows, 1st, that the disassociation of the organisms, which, in man, is only transient, is, on the contrary, fixed and permanent in animals. 2d, That the various organic forms resulting from this disassociation, fleeting in man, are constant and fixed in animals. 3d, That animals, considered with regard to the formation of the organisms, permanently represent the embryos of the human race.

This mutual relation of organogeny and comparative anatomy leads to that of zoogeny. An animal is a compound of organs, as an organ is a compound of organic elements. Association or homozygy unites and harmonises these organs together, in the same way that it combines the materials constituting them. Such being the case, can the formation of the animal be brought under the same laws as that of the organ, or, in other terms, are organogeny and zoogeny mutually related to one another? This question presents great interest, for, according to the system of pre-existences, it was taught that animals, as well as organs, were pre-formed in every part; such as they now appear, so had they always been at the various periods of their existence. We must then enquire, in the first place, whether there really exist elements of animals, as we find elements of organs; whether these zoogenic elements can become combined and associated one with another so as to produce a variation in animality, in the same way that the organic elements are associated and combined to vary the nature and form of organs. The solution of these questions may, methinks, be traced in a certain manner by organogeny. I may remark, that there are elementary animals of the most simple kind, as also there are primitive tissues and organites formed by the most simple combinations. These simple or primitive animals have been designated by the term *zoonites*, by MM. Dumal, Moquin,—Sandon, and Dugès. The *zoonites* are in some sort diminutive animals, as the *organites* are diminutive organs; and in the same way that an organite may carry on its function in

an isolated state, and concur by its association to a common action, so may a zoonite live isolated, as it may also by its association bring its share of life to a common stock. The *monades*, the *volvoces*, the *acephalocysts* are free zoonites. The difference which exists between an organite and a zoonite depends then less on their constitution than on their dependence or independence. In this consists the fundamental principle. An organite is always dependent, its life is always subordinate to that of the individual of which it forms a part; a zoonite is always independent, it has a life peculiar to itself. So that by conceiving an organite which had lost its dependence, we should picture to the mind a zoonite, in the same way that a zoonite ceasing to be independent would become converted into an organite. Thus the ovules composing the ovary in the mammifera, in birds and reptiles, are organites; they are parts possessing a common character. The immediate result of impregnation is to separate the ovule from its associates, to isolate it, and render it independent. It is then in this state a zoonite capable of passing freely through its various evolutions. We may, however, have the inverse of this take place in nature; for we sometimes see zoonites as the *monades*, the *volvoces*, the *ascidiæ*, and even the *biphora*, which have a separate and independent existence, become united to others of their own species; from independent they become dependent beings, quitting their individuality to become associated with their fellows, and thus passing from the state of zoonites to that of organites. This important fact may, perhaps, throw some light on organogeny. For, in this point of view, what should prevent us from considering the serous membranes or vesicles, before they become associated with the organs, as species of zoonites which by their association become organites. I might also show that the serous vesicles which become accidentally developed are and remain zoonites (*cysticerci*); but my object was to establish that, in zoogeny, the zoonites or elementary animals may exist in two different states; that they may be either free or associated, very similar to the organites or elementary organs which we find either associated or disassociated in the phenomena of organogeny.

COURSE OF LECTURES ON THE THEORY AND PRACTICE OF MEDICINE.

Delivered by C. J. B. WILLIAMS, M.D., F.R.S., Pofessor of the Practice of Medicine, and of Clinical Medicine, at University College.

GENTLEMEN,—By a careful comparison and discrimination of the details I have given with regard to congestion, determination, irritation, and inflammation, you will be able, in all ordinary cases, to make an accurate *diagnosis* between them; and to do this with readiness is, as you must at once see, a matter of no little importance in practice. I shall now only give you a very brief summary of the leading features:—We found that in *congestion* there is, as compared with inflammation, little pain and heat, and that the redness is much less intense; also, that there is less tendency to the production of changes in the structures affected, and that the fever accompanying inflammation is either absent altogether, or else assumes a much lower character. We found that in *determination*, there is likewise no alteration produced in the structures, and very little in the secretions,—that the fever is much more evanescent than in inflammation, and that the pain is much less considerable. The increased local pulsation and various other little points distinguish it from congestion. The next state requiring to be carefully distinguished from inflammation, is what has been termed *irritation*, by which, in the present case, is meant simple exaltation of the property by which impressions are excited in a part, or communicated from one part to another. Now, in nervous subjects, as we have already noticed, causes *un*connected with inflammation, may excite all the sympathetic signs that inflammation commonly produces; for example—inflammation of the stomach causes vomiting, which depends upon excitation of the stomach, abdominal muscles, and the diaphragm, and yet, as you all know, vomiting may arise in numberless instances, in which nothing like true inflammation can be suspected; it may arise from congestion, from the presence of various foreign substances, from even mental impressions, and, in short, from any cause that will be productive of *irritation*. It is clear, then, that we must find some symptoms or signs that are *peculiar* to inflammation before we can be justified in stating, that inflammation is present. In simple irritation there is no *heat*, no *redness*, no *swelling*, although there may be very severe *pain*. Irritation does not produce much perversion in the functions of a part, whereas this perversion is a very leading character in the influences of inflammation; for example, suppose a case in which lumbar pain was experienced in a severe degree; that the testicle was retracted; that the loins were tender on pressure; and that, in consequence of the severe pain suffered, the heart's action was somewhat increased, and general excitement of the constitution was present, in fact, that there was slight *fever*, how should we decide whether the cause of the symptoms was *inflammation* of the kidneys (nephritis), or whether all was owing to simple *irritation* of the nerves without any inflammation whatever? We should naturally have immediate recourse to the condition of the *function* of the kidney, and ascertain the state of the *urine*. If, on examination, we found it copious, clear, and of usual and healthy colour, we should conclude at once that the kidney was not the seat of *inflammation*. Thus you see the state of a secretion may be the point upon which your diagnosis would turn. If any mechanical irritation, however, existed, such as a calculus, we might find the appearance of the urine altered by the presence of *mucus*, although there was *no* inflammation. Again, you know, that *fever* is a great characteristic of inflammatory action, whereas, in irritation, there may be entire absence of hardness or sharpness of pulse, heat of skin or continued perspiration and the like. It is true the heat might be increased temporarily, but it would not be *permanent* like that of inflammation. It has been supposed that the serum from an inflamed serous membrane always contains a number of granules (epithelial cells), which is not the case when only *congestion* is present. So much for the *diagnosis* of inflammation. We shall now proceed to the subject of its *prognosis* or *probable termination*. The probable event of inflammatory disease must depend upon its *seat*, *extent*, *advancement*, and the nature of its *product*, as well, of course, as upon the stamina of the individual in whom it occurs. With regard to the *seat*, I need scarcely say, that the more important the organ, the more dangerous, cæteris paribus, will be the inflammation, and, as a consequence, the less favourable will be the *prognosis*. It is also equally obvious that the greater the extent of surface over which inflammation prevails, the less likely it is to be subdued. Again, as to the *advancement* of the disease, our prognosis would be much more favourable in the *early* stages, because at that period our remedies have by far the greatest influence. The state of the *functions* generally is an important guide to prognosis; the less these are affected the more favourable will be our opinion. I shall notice the products of inflammation presently.

To sum up, the prospect is good when the previous health has been, and continues, sound—when there is little constitutional derangement—when the inflammation is slight—when the sensorium is little affected, and the secretions not much perverted. Under these circumstances the antiphlogistic treatment is most effectual, and can be best borne. Inflammation occurring in good constitutions ought always to be cured, and when the organ affected is not important. On the other hand, the prognosis will be *un*favourable, when the inflammation occurs in *weak* constitutions, whether such debility arises from age, from excesses, or from previous disease; when the inflammation is far advanced, and the system has been long suffering—when there is some depressing influence on the powers of the system as an animal *poison*, or something modifying materially the nutritive processes, as are found to be the case in *scrofula*; when the secretions are greatly disordered, and an important organ is extensively affected—when symptoms, indicating a low condition of the habit, such as brown tongue, fetid urine, feeble pulse, and the like, are manifested, Under all these circumstances we must be very cautious how we hold out sanguine expectations of a favourable result. One great reason for a bad prognosis when the system has become weakened, is, that the season for employing antiphlogistic measures has passed away.

We have next to notice the ordinary ways in which inflammations may be considered to produce a fatal result. We shall find that they may be divided into *four*. In the first place inflammation may prove fatal by directly impeding the *vital* functions; thus, inflammation of the brain causing effusion and consequent pressure, so that the cerebral function, which we know is essential to life, becomes impaired and destroyed. Again, inflammation of the lungs proves fatal by the injury produced upon the all important function of respiration. We may say that death is produced in both cases by asphyxia. Inflammations affecting the heart, kidneys, &c. are also fatal, by impairing necessary functions. The same is true of the intestines. The second method of termination is by the sympathetic depression in the action of the heart. Thus inflammation of the peritoneum causes great prostration, and the patient dies of syncope. A third termination is caused by means of the *products* of inflammation *poisoning* the system. Examples of this are seen in the absorption of gangrenous matter—pus, and the like. Erysipelas and hospital gangrene may prove fatal on the same principle. The fourth, and last method, is *gradual exhaustion* of the *whole vital powers* Thus in cases of *extensive* suppuration, the strength of the system is gradually reduced, so that no vital energy remains, and death, as a necessary consequence, takes place. Abscesses in the liver, lungs, &c., may also, by their constant drain upon the constitution, end in the same way.

It now remains for us to consider, and that very attentively, the *treatment* of inflammation, and seeing that the disease itself is so complicated, and consists of various elements, it is only reasonable to expect that the treatment founded upon the elements should be somewhat complex also. Some of the elements may be regarded as more essential than others; thus *congestion*, *determination*, *exaggeration*, and alteration of the *nervous* functions appear to be *essential*. The *general* functional derangement and excitement of the heart, constituting inflammatory fever, and the altered condition of the blood may be regarded as less essential. Each element may be present in different proportions in different cases of inflammation, and each may be opposed by different remedies. We find also various *combinations* of the elements. I have prepared a tabular arrangement for you, which I think will give you a more concise view of the elements and their treatment.

ELEMENTS. INFLAMMATORY	ANTIPHLOGISTIC REMEDIES DISEASE.
Local Inflammation.	
Congestion	Stimulants, Astringents.
Determination	Derivants, Depletion.
Iritation of Versels	Sedatives, Derivatives, Evacuants.
Iritation of Nerves	Narcotics, Counter Irritants.
Fever.	
Increased action of Heart and Arteries	Blood-letting, Sedatives, Relaxants
Diminished Secretions	Evacuants, Alteratives.
Change in the Blood	Blood-letting, Alteratives, Evacuants.
Results of the Inflammation.	
Effusions	Evacuants, Rubefacients, Discutients.
Softening.	
Suppuration.	
Ulceration.	
Gangrene	
Adhesion, Induration, &c.	

When one irritant causes dilatation of the vessels to which it is applied, a second one may produce contraction, and thus disperse the accumulation to which the first gave rise. Thus we may often treat successfully the first or congestive stage of inflammation by astringents or stimulants, as in slight inflammations of the eye. The operation of these two classes of remedies is distinct, although they are frequently confounded. Thus simple astringents, as cold, acetate of lead, &c. act, by diminishing directly the calibre of the capillaries.

Whereas stimulants operate by causing determination to the congested capillaries, and thus sweeping away the accumulated blood. I readily ascertained this last mentioned fact by causing congestion in the web of a frog's foot by means of a little capsicum, and then applying a drop of essential oil, the result of the latter application was to enlarge the capillaries by producing determination to the part, and thus sweeping away the congested blood. This is rather dangerous work in practice, yet when judiciously regulated may be highly useful in putting a stop to threatening inflammation. In slight cases of sore throat, astringent and stimulant gargles are often beneficial. Cayenne is with many a favourite remedy, and it operates not merely as an astringent, but it relieves the overloaded vessels by increasing the secretions. Again, in slight disorders of the stomach and bowels, in which a low degree of inflammatory action is probably present, emetics and purgatives are beneficial; these stimulate the parts, and cause the secretions to be augmented. Nitrate of silver may be useful in cases of slight ulceration of the intestines. It has also a remarkable influence in *erysipelatous* inflammation. Some suppose that its application causes a new kind of inflammation, which arrests that previously existing; others say that the progress of the erysipelas is stopped by the nitrate of silver causing lymph to be thrown out around, whereby the first inflammation is circumscribed. The utility of stimulants is seen in the good effects often produced by stimulant inhalation in some cases of bronchitis. Heat and cold are frequently used in inflammation—cold astringes—heat stimulates; but it acts chiefly as a derivant on the adjoining vessels. If there is a considerable determination, these remedies will fail to produce much benefit. Evacuants and derivants must be used; we may try bleeding. In tonsillitis we may scarify, and then use astringents. If there is much blood in the system, this must be diminished (as well as removing blood from the immediate seat of inflammation), although there may be only little inflammatory *fever* present. When, in addition to these, there is considerable *pain* and *nervous* irritation, the treatment must consist in the addition of *sedatives*;—of the local sedatives there are, perhaps, few more effectual than cold; solution of lead is very useful. In inflammation of the stomach, it is very beneficial to swallow ice, also to drink cooling saline solutions, such as nitre, citric acid, &c. These can only be trusted of course in *slight* inflammations. When inflammation is chronic, we may employ more decided astringents, such as the nitrate of silver, sulphate of zinc and the like.

EXTRACTS FROM FOREIGN JOURNALS.

(Translated from the 'Gazette Medicale' For the 'Medical Times.')

FRENCH.—*Extraordinary case of Catalepsy, with Transposition of the senses, observed at Caen.* By Dr. Duvard.—Mlle. Melanie, born of parents who had always enjoyed good health; one of her elder sisters, however, had died of pulmonary phthisis, and a younger sister had been for some time ill. Mlle. Melanie herself possessed a strong constitution, and was always in good health up to twenty-one years of age. About this period she was attacked with a dry cough, accompanied with pains in the chest and head-ache; she was not however, obliged to keep her bed till six months later. In January, 1841, she was affected with pleurisy of the right side, which confined her to her bed for three weeks, at the end of which time she got up imperfectly cured. Since then, she has constantly suffered in the right side of the chest; the menstrual flux at first diminished, has since become totally suppressed. In the month of July, 1841, I was called to attend her for the first time; she then presented all the signs of pleuritic effusion (constriction of respiration, dry and frequent cough, unnatural enlargement of the right side of the chest, dull sound on percussion, absence of the respiratory murmur at the base of the lun and ægophony). The patient had still considerable *embonpoint*; her countenance was ruddy and she was quite free from fever. The application of leeches to the upper part of the thighs and blisters to the diseased side, produced considerable improvement. The patient then objected to any further treatment, as she was able to keep about: but some weeks afterwards she was affected with a spitting of blood, which necessitated two bleedings at the arm. In a short time, the pains in the chest, the head, and stomach, became again very intense, when the family called in Dr. Vastel, who agreed with me as to the presence of a pleuritic effusion. A large seton was applied to the lower part of the chest. The patient, who had several times previously refused to submit to this operation, gave her consent with great difficulty; she laboured under great nervous irritation, which was augmented on the following days, and which I attributed to the circumstance of the seton having caused acute inflammation of the surrounding tissues, but unattended by suppuration.

Six days after the application of the seton, the patient who, for fifteen days previously had had no alvine evacuation, was as it were compelled to use a lavement, to which she had always hitherto objected, in spite of all solicitations. Some hours afterwards, Mlle. Melanie, who had never before been attacked with hysteria, experienced a fit of great violence, which lasted several hours. The next day, she took three drops of croton oil, which produced copious evacuations, and on the third day she felt relieved and asked for something to eat. A few hours after taking food, however, the hysteria reappeared with renewed violence, and on the succeeding days the patient had several fits every day, each attack lasting two or three hours; these paroxysms constantly occurred after her taking food, which she obstinately persisted in doing, notwithstanding all remonstrances. The seton, which had not suppurated, and which caused acute pain, was withdrawn eight days after its application, without, however, having any effect over the hysterical fits, which were generally proportioned in length and violence to the quantity of food taken by the patient. These attacks always began in the same manner: the patient after experiencing for some time greater pain in the chest and weight at the stomach than usual, began suddenly to scream out, and her body became bent backwards, as in opisthotonos, so as to form an arch, the extremities of which were constituted by the crown of the head and the soles of the feet resting on the bed; she remained for some minutes immoveable in this position. Then, unless restrained, she would throw herself off the bed on to the floor and roll about in agony, striking her chest and stomach with her hands, or knocking her head against the floor. Sometimes she dragged herself upon her knees and elbows round the chamber with great rapidity until her strength was completely exhausted. Then she became calm for a few minutes; but soon renewed her cries and convulsive movements, especially on hearing any unexpected noise, as the violent slamming of a door, the rolling of a drum, the barking of a dog, &c. Frequently when in her calm moments, the persons around her sang a hymn she knew by heart, she would join her voice with theirs, without appearing conscious of what she did, and then she would sing with greater sweetness than in her lucid moments. After thus singing, sometimes, for several hours, she would fall asleep, and on waking in her full faculties, would have no remembrance of what had happened. Six days after the appearance of the hysteria, the patient was suddenly struck dumb, and for three days was unable to articulate a single word, being obliged, in her lucid moments, to write down what she had to say to those about her. She recovered her speech on the fourth day, after a violent hysterical fit; then, after speaking a few words to the surprise of all present, she experienced another fit which lasted three hours, after which, she, for the first time, fell into a state of catalepsy, on the 30th of August, 1841.

From this period Mlle. Melanie had each day several attacks of catalepsy, alternating with hysteria, and which lasted about half an hour each. During these cataleptic attacks, there was complete insensibility of all parts of the body; the limbs easily assumed and preserved the positions, however fatiguing, which were given to them; the respiratory movements were imperceptible; the pulse was scarcely perceptible at the radial artery, and the contractions of the heart, which were very feeble, were from sixty to seventy in the minute. After some days, the cataleptic paroxysms became longer, lasting several hours each, but not without interruption; for every time the patient coughed, which frequently took place every ten or twelve minutes, she performed some respiratory movements; sometimes she turned her head from one side to the other, or else raised herself into the sitting posture,—at other times she jumped out of bed, stood at its extremity without opening her eyes, and balanced herself upon one or both legs,—or else she walked about the room, or placed herself upon some eminence, where she usually assumed some fatiguing though graceful posture. Her countenance had, during the whole cataleptic condition, an air of sweetness and satisfaction. She preserved these assumed attitudes until affected with a new paroxysm of cough, or until carried back to bed. Although her eyes were constantly closed, she never ran against any obstacle or injured herself. One day during a fit of coughing she jumped out of bed and flew towards a window, which she opened before any one could prevent her; but at the moment that she appeared about to leap outwards, the cough ceased, and the patient relapsed into a state of cataleptic immobility, with one foot placed outside the window and the other on the floor. She remained in this position until carried back to bed. The termination of each cataleptic attack was indicated by the respiration, which became gradually more free until the patient opened her eyes and recovered her intelligence. The return of the hysterical fit might also be foretold by watching the countenance of the patient, for the chin and lower lip were agitated by convulsive movements for some seconds, or even a minute before the commencement of each attack. After the cessation of the catalepsy, or hysteria, she recovered her full faculties and complained only of fatigue beyond her usual pains. Sometimes, during her suffering, she would regret not being in a state of catalepsy, during which she felt no pain. Frequently, during the lucid intermissions in the night, she would get up and work for several hours at her embroidery. Then, when all about her were asleep, she would take the keys and search the house for food, which she eat with avidity, although she knew that it rendered her attacks longer and more frequent.

For eight days, the usual attacks of hysteria almost entirely ceased, and were replaced by paroxysms of dyspnœa which lasted about half an hour each, and which appeared to be produced by the spasmodic contractions of the diaphragm. During these attacks, the patient breathed from eighty to an hundred, or even an hundred and twenty times in a minute,

which fatigued her much more than the other convulsive movements; the pulse ranged from sixty to seventy.

Five weeks after the commencement of the catalepsy, Mlle. Melanie had several attacks of natural somnambulism, getting out of bed without opening her eyes, walking about the room, arranging the furniture, &c., and entering into conversation or answering the questions addressed to her, even with more truth than in her waking state.

On the 12th of October, some days after the first attacks of somnambulism, I found, at my morning visit, Mlle. Melanie in the cataleptic state, and on placing my hand upon the epigastric region, I observed her face assume an expression of pain. I then applied my mouth to the pit of the stomach and addressed some questions to the patient which she answered correctly, to my great surprise; for although I had read of some cases of a similar kind, I had hitherto refused to believe them, thinking the authors were themselves deceived or wished to deceive others. During this visit which lasted an hour and a half, I made numerous and conclusive experiments which convinced me of the transposition of the five senses to the epigastrium. All the experiments which I made at this visit and the two following ones, with a view of ascertaining whether the palms of the hands or the soles of the feet possessed the same sensibility as the pit of the stomach, produced no result, and yet, two days afterwards, these regions became equally sensitive. In the evening of the same day, I renewed these experiments in the presence of several witnesses, who were equally astonished as myself. Lastly, I continued repeating them every day, and several times a day, for the space of two months, varying them in every possible form, and adopting every precaution to guard against deception, although from the character of the patient I could not suspect her of having any intention to impose on me. Here was the case of a religious young person, who, before her illness, had never heard of catalepsy or animal magnetism, and who, when the latter agent was spoken of as a likely means to cure her and its nature explained, had always called it *folly*.

In this cataleptic state, the muscles of the trunk and limbs presented three different conditions; sometimes they easily assumed and steadily preserved the positions given to them, however fatiguing or fanciful. This was the most frequent condition, and, in fact, the only one observed during the first month. When in this state the eyes were constantly closed, but could be opened by the operator. At other times the muscles were contracted with tetanic rigidity throughout the whole body, so that the strongest efforts failed in overcoming them. The eyes were then open and fixed, but could be readily closed. The tongue was protruded from the mouth, and was only withdrawn within the teeth on compressing the nostrils, so as to compel the patient to respire by the mouth. Lastly, in some conditions of the muscular system, the limbs would readily assume whatever position might be given them, but immediately on abandoning them, they became obedient to the laws of gravity.

Sensibility was totally absent in the integuments and subjacent parts, excepting at the pit of the stomach, the palms of the hands, and the soles of the feet. Thus the patient showed no signs of sensation on pinching or pricking the skin, on drawing the hair, titillating the nose, &c.; but if the before-excepted parts were touched even with the feathers of a quill, the patient immediately withdrew the part touched, and by her countenance evinced her displeasure. On applying the knob of a Leyden jar, charged with electricity, to the sensitive parts, the patient gave a violent jump, and sometimes instantly awoke; but she remained immoveable when the electricity was discharged upon any other part of the body.

The sense of hearing seemed perfectly absent at the ear itself, but on sounding a bell over one of the sensitive regions, her countenance indicated that she heard the noise. On speaking to her by placing the lips upon either of these parts, she heard what was said to her, although spoken in so low a voice that the words could not reach her ears. She answered all the questions addressed to her, but her voice was always so low, that it was necessary for a third party to apply his ear to the lips of the patient. It was not necessary for the patient to hear what was said, that the lips of the operator should be applied in immediate contact with the sensitive parts. I often made use of a long stick or rod of iron, placed as a conductor of sound between my mouth and the foot of the patient, who heard and answered my questions, although I spoke so low, that persons placed between me and the head of the patient, could not understand what I said. The answers which Mlle. Melanie made to the questions addressed to her in this condition were quite as *apropos*, or even more so, than she could have given if in her waking state, for her memory seemed to be better while in the cataleptic paroxysm. But when affected with the tetanic spasm, the tongue and other parts subservient to speech were unable to execute any movement; the patient said at the termination of the paroxysm, that although she had heard what was said, she was unable to give any answer.

The taste and smell were totally wanting in the organs by means of which they are usually exercised; but they were greatly developed in the sensitive regions. Thus substances of an intensely disagreeable or powerful flavour might be placed upon the tongue without producing any indication of her tasting them; and the nares might be filled with tobacco, assafœtida, the fumes of ammonia, &c., without inducing any effect. But on placing any of these substances upon the sensitive regions, the patient immediately perceived their flavour or odour, and her countenance indicated whether they were to her taste or not. She would also when questioned, name what the substance was thus submitted to her examination, and would answer whether it were good or bad. On applying some ammonia to the soles of her feet, she complained of its strong odour, which almost immediately made her cough, whilst she remained immoveable when some of the liquid was dropped on her leg, and even left so long as to produce vesication of the skin.

Although the results of my first experiments led me to believe that there was also in this case a transposition of vision as well as of the other senses, I afterwards became convinced that such was not the case, and that what I had at first considered as the effect of vision, was merely the result of an excessively developed sensibility of touch. On separating the eye-lids, and touching the globe of the eye, the patient attempted to close the lids, and if, whilst they were separated, a light was approached to the eye, the iris slightly contracted. Still nothing indicated that the patient saw what was around her, and the act of passing any instrument in front of the eye gave rise to no movement. During the tetanic spasm, the eye-lids and iris were perfectly immoveable. On placing any object upon one of the sensitive regions, and asking the patient whether she could see it, she answered in the affirmative, and almost invariably named the object, or else described it with sufficient accuracy. Thus she always recognised a watch when placed at the pit of the stomach, or in the hand; she invariably told whether the watch were of gold or silver, and whether it was going or was stopped. She could also tell pretty correctly the hour of the day as exhibited by the watch, but she was constantly deceived when the hands of the watch were deranged, so that they no longer corresponded to the true time. At the second sitting, she succeeded, after complaining for some time that it fatigued her to read, in spelling the word *commerce*, written in large letters, and placed upon the pit of the stomach; but in subsequent experiments she could never distinguish the letters of the alphabet written separately, and placed successively upon one of the sensitive regions. When asked how many persons were in her room, she always answered correctly, and would name those whom she knew; but she was often deceived when asked to point out the position and occupation of each of these individuals. Whenever I asked her if she could see the seat of her disease, or if she could inform me what was necessary to cure her, she answered in the negative, saying it was my affair, and not hers, and that I ought to know better than her, the nature of her disease.

Effects of Treatment.—Bleeding by the lancet, by leeches, and by cupping, frequently relieved the disease, allaying the cough, the pains in the chest, in the head, &c.; but the nervous symptoms were always rather augmented than diminished after the abstraction of blood. Flying blisters always allayed the cough and pains in the chest, so much so that probably the patient would have been cured had she been willing to have continued the use of them. Purgatives and emetics relieved the pains in the stomach whenever they were employed. After their action, the fits of hysteria and catalepsy were less frequent, as well as shorter; but the very intimation of employing a lavement was sufficient to throw her into a fit of hysteria. Antispasmodics and narcotics never produced any relief, even momentarily. These latter remedies were administered both by the mouth and by the endermic method. I endeavoured to magnetise the patient, and in the three first sittings I thought that I had succeeded in arresting the fits of hysteria by this means. She was put to sleep, and remained in this state for several hours each time; but in the succeeding sittings all my efforts were useless, and I was able to produce no effect. Electricity appeared to produce more favourable results, with regard to the nervous affection, than any other means employed. When the patient, being plunged in the cataleptic state held the two poles of an electrical machine in her hands, the shocks she experienced were much weaker than would have been felt in a state of health. Still these shocks were always sufficient to wake her after a few minutes; she then pushed the poles away and relapsed into a cataleptic state, when I recommenced the experiment, and after waking her thus several times, she would, in about half an hour, recover her full faculties. From the first day that the patient was thus treated by electricity, the fits of hysteria and catalepsy, especially the latter, became less frequent and shorter, and after about three weeks, she used sometimes to pass over the twenty-four hours without experiencing any paroxysm. In the month of December, she found herself well enough to go home to her parents, who lived twelve leagues beyond Caen. Still, the cough and pain in the chest were almost in the same state as six months previously.

Present Condition.—Mlle. Melanie, who has for the past three months been staying at her own home, and has refused to submit herself

to any treatment, is, I am informed, in almost the same condition as when she quitted Caen. She is constantly tormented with the same dry and frequent cough, with the pains in the right side of the chest, and the head ache. Her digestion is better, in consequence of her taking frequent exercise on horse-back and in a carriage. She preserves her *embonpoint* and fresh look. The attacks of hysteria and catalepsy are much less frequent; but any opposition offered to her, or any sudden emotion, instantly cause these fits to re-appear. She is especially subject to them at the period of menstruation, which, after having been suppressed for several months, has re-appeared, although in small quantity.

The above case, says the editor of the *Gaz. Medicale*, is exceedingly interesting under several points of view. 1st. The patient, although labouring for fifteen months under chronic pleurisy and dysmenorrhea, and finally amenorrhea, had preserved her colour and *embonpoint*. 2d. There appeared to be a constant connection between the state of the digestive tube and the nervous symptoms. These latter were constantly relieved by the employment of purgatives; and it was especially when the stomach was full that the fits of hysteria were most violent. The digestion appeared to be very weak, for on several occasions the patient vomited food taken forty-eight hours previously, and which had undergone scarcely any alteration. 3d. The cataleptic state ceased immediately that the cough awakened the pain in the right side of the chest, showing that the internal organs were not like the external, devoid of sensibility.

TO CORRESPONDENTS.

We are still receiving letters in shoals about the New Regulations. Our correspondents must be referred to the resolutions of the College, published among our advertisements last week, and to our observations thereupon. What kind, or what amount, of preliminary professional education the court of examiners require from gentlemen long in active practice, we know not—nor do they appear to know themselves—for they demand "what may *satisfy them;" i.e. we suppose, a something in the future not yet decided on, but which will probably rise or fall with the healthy state of the digestive organs of the examiners. If there be any absurd rigidity shewn in the requisition, the object of the change will be entirely defeated, and what was meant for a boon to a great body of country practitioners, and which we welcomed as tending to make more compact and united the great body of our profession, will prove but an unhandsome fraud, most injurious to the happiness of numbers whose hopes it only excited, to blast. Sir Benjamin Brodie, we somewhat fear, has out-generalled our friend Guthrie.*

Fulvus—Chiros—M. N.—Dr. W.—Mr. S. P. T. Argus—*declined.*

Several communications have been received.

Adscriptor *can recover for that portion of his attendance which he can prove to be medical.*

H. N. D.—*In a similar case, on an indictment for murder, the jury were directed "that if either of the prisoners sustained the principal by his advice or presence, or if they thought he went down for the purpose of encouraging the unlawful conflict, although he did not say or do anything, yet if he was present, and was assisting, &c., he will be guilty of the offence"—and the prisoners were found guilty.*

We had thought of publishing the report of the French Academy of Medicine on Orfila's experiments, but the lectures of the celebrated French chemist, (given in our last vol.) are so ample in their elucidations, that the addition now appears to us unnecessary.

Mr. Nottingham's sixth lecture on Operative Surgery—Mr. Smith's case of Spasmodic Stricture of the Urethra, and the observations of Veritus next week.

We shall commence next week the beginning of a series of about six papers on "the Diseases of Cotton Factories" by our esteemed contributor, Dr. Charles Clay, whose articles on the Extirpation of Diseased Ovaries, recently published in our journal, have excited such marked interest on the part of British and Continental surgeons.

THE MEDICAL TIMES.

SATURDAY, DECEMBER 17, 1842.

——— Give order that these bodies,
High on a stage be placed to the view,
And let me speak to the unknowing world
How these things came about.

SHAKSPEARE.

WE proceed, according to our promise of last week, to burn out that nest of disease—that lair of pestilence—the Tabernacle Grave Yard, Tottenham Court-road. Approximation, even mentally is so foul that we shall endeavour to make short work of it.

This stinking mass of putrefaction—this dead man's dunghill—ferments, and seethes, and pours out its steaming gases into one of the most crowded of metropolitan neighbourhoods, and alongside one of the most incessantly trodden of metropolitan highways. The vampire of the establishment is a Mr. Nash; a gentleman who, doing the honours with the zeal his polished namesake shewed for the waters of Bath, catered for this pet spot with a cleverness of diplomacy, which, though "man wants but little *there* below," early, very early secured for it more customers than it could supply packing place for, and, subsequently, called into exercise more mechanical ingenuity in the grave-diggers than was required to make the fortunes of an Arkwright—nay, more than has been required in the diggers of any other grave-yard in London, excepting only that, whose odorous exhalations, rising like the sweets of "incense breathing morn," supply an atmosphere and "ventilation" to the *immortal* inmates of Dr. Todd's "best possibly situated" of hospitals. We know not how this spot escaped notice in Mr. Walker's valuable book, and in the Report of the Parliamentary Committee — BUT YEARS AGO—*and several years, too*, as we are prepared to prove, it was saturated, *plugged* with human decomposition. But Mr. Nash is the *beau ideal* of pious and ingenious sextons. A charitable, religious, soul-saving man who never yet, in a case of real need, failed to help a brother who was in a position to help himself, he wrestled with nature and conquered seeming impossibilities in his Tobit-like FUROR of burying the dead. Though the ground was thus, as it were, unchangeably pre-occupied, no man can say that Mr. Nash turned back sorrowful the applicant for a grave, though he were the last of fifty in the day, for any imaginable reason, save one—*that he had not the money to pay for it*. But to be just to Mr. Nash we must be less general in our laudations, and we have one incident to mention, which, if taken, as it may be, as a sample of his general management, will do, in a few words, more justice to his high characteristics than an article as long and turgid with praises as a French *Oraison Funebre*.

Some short time ago, a Mr. Moreland, builder, in Old Street Road, St. Luke's, lost a female relative. A man of some acquired wealth, he seized the occasion of her death for the erection of a *family vault*, and the site chosen—we never dispute about the vagaries of rich men's tastes—was the Tabernacle grave-yard, Tottenham Court Road. The precise spot chosen, the grave-digger *began* his work. What was the *beginning?* There are railings separating the *dead* within, from the *living* population without. These, raised some time ago, not only allowed the gases to pass out, but the people to peep in. The railings were carefully blocked up—in the words of our informant, "boarded all over." But there were houses around—high houses, overlooking the yard, and though the inmates might on *ordinary* occasions be kept ignorant of what was going on, by the sexton---we beg pardon, the digger—using very late or very early hours; not so now, for the new grave was urgently required, and there could be no remission of toil. *A tarpauling scaffolding was, therefore, erected over the grave*, which "let the light in, but kept out eyes." Our readers, perhaps suppose, that in the hurry for the completed grave, Mr. Nash—or the chapel clerk, or minister, or Mr. Moreland himself had to aid in digging—and that these were delicate precautions to save them from observation in so unusual a position. Not so. The usual grave-digger did all the work, and what occurred while he did so, shewed, that there was a better reason for these expensive and troublesome preliminaries. The grave-digger threw out but a few shovelfulls of earth ere he came across some children's coffins. These were soon disposed of; they were crushed into a hole readily dug for them. Next came, at the head of the grave, a tier of six or seven coffins, fresh and solid—buried but a few months. The knife, the saw were used—the heads, the feet, were respectively severed—the different members forced into the narrowest hole that could be made to hold them. At the foot of the new grave, the heads of *two coffins* jutted in. How were these got rid of? The intruding portion was partly sawed, partly chopped away—the wood was thrown up, and the separated extremities, forced back into the remaining portion of the coffins. Far into the left side of the new tomb the thinner end of a coffin abutted. It was severed of course, and a woman's legs wrapped in lamb's wool stockings, perfect as at the moment of death, were exposed. The former, the customary course of treatment, was repeated. This is the briefly given history of *one* grave-making, in which the sickness — the half-asphyxia — the terminating beastly drunkenness of the digger — the liquid animal decomposition — the wheelbarrow loads of bones and old coffin wood, and a hundred similar circumstances are not even mentioned. But thus unexaggerated —thus curtailed—what is the history's impression on our readers? Do they see now

the reason for the *boarded* railings—the tarpauling scaffolding? Do they catch a better glimpse of what makes a good London sexton? And now what think they generally of the decent, the healthy, the enlightened system of metropolitan inhumation? If it disgusts much, it *depraves* more. But enough of this Tabernacle of unholies!

PENCILLINGS OF LIVING MEDICAL MEN.

ST. THOMAS'S HOSPITAL, MR. GREEN.

The savage rage to destroy the ancient monuments and cathedrals of England spared not many of our hospitals, the relics of the piety and benevolence of our forefathers. The endowed and noble institutions erected for the relief of the indigent and afflicted, participated in the general ruin. Their ample revenues invited the hand of heartless spoliation. Fortunately for humanity, St. Thomas's Hospital, which we are about to sketch, escaped: its history is calculated to cherish and keep alive that pure, exalted, and sacred spirit of charity for which this country has ever been distinguished. Egypt may boast of her pyramids, mighty monuments, of the skill and vanity of her children, with feelings of proud and sublime exaltation.—England can point to this glorious record and evidence of the early inherent, hereditary, and imperishable beneficence and goodness of her inhabitants. Knox said of the cathedrals: "the best way to prevent the rooks from returning is to destroy their nests." Dugdale relates instances in which his fanatic followers disregarded his vile instigations, and that even in the times of the Commonwealth, when all vestiges of the piety and benevolence of our ancestors were sought to be erased, that many of the humblest classes shrunk from laying their sacrilegious hands upon many endowed institutions. From some such feeling, as well as from the protection of the citizens of London, the property of St. Thomas's Hospital escaped state appropriation. The priors and canons of St. Olave, and Peter de la Roche, Bishop of Winchester, were its founders. He retained upon its dedication, a visitorial power, or guardianship, over this institution, and bestowed property to the value of £343—a sum which, if calculated according to the value of the time, was amply sufficient to render it capable of fulfilling the beneficent intentions of its founders.

With it was connected also the almonry, a house of hospitality, an asylum for the accommodation of poor wayfaring pilgrims. This was about the year 1200. The names of those who contributed to this glorious work of charity were lost in the general wreck and confusion of ecclesiastical property at the time of the reformation, which, in its zeal for principle, did not forget to possess itself of the property of the church.

The doctrine of the Church of Rome, which affirms that the practice of charity was essential to salvation, was instrumental in creating and supporting such institutions.

In the reign of Edward VI. a charter was granted to the corporation of London, giving it the entire disposal of the confiscated edifice of St. Thomas; it was dated 1551. The corporation, which paid a sum of money for it, added to its funds, which were impaired by the pious propounders of the reformation.

The officers who received salaries were—the chaplain, £10; the physicians and surgeons, each £15; the steward, £6; the butler, £6. The lord mayor and citizens nominated from themselves the requisite number of governors. It was destroyed by the fire of London. It was rebuilt by the liberality of the citizens, who, in the short space of three years, contributed thirty-seven thousand pounds for that purpose, Clayton, Guy, and Frederick, being the largest donors, whose generosity shed a lustre upon the land that gave them birth.

St. Thomas' Hospital consisted of two quadrangular red brick buildings. In the first stands the statue of Edward the VI.; in the second, that of its great benefactor Clayton. There are detached houses for the officers of the establishment, with a detached building for accidents. The part which faced the thoroughfare leading to London Bridge has been removed, and its site is occupied by two wings running north and south, which are of the most modern style of architecture; lofty, spacious, well ventilated, they are on a level with the new street, which is several feet above the new square. The staircases are stone, the whole structure grand and massive. The wards are double the height and width of the old buildings. The beds are farther apart, and the comforts of the patients, of the sisters, or attendants, are not sacrificed to taste or design. It is a credit to those to whom the administration of the hospital is entrusted, and when the whole plan is carried out, it will be a magnificent monument of the munificence of the citizens of London, with whom the flood gates of charity once opened, golden streams flow in from a thousand sources. The first idea is generally to administer relief to the suffering; little care or wisdom is bestowed on the management of these funds, and from this neglect all the "embosomed sores and headed evils," gross corporate, and private embezzlement, nepotism, favouritism, incapacity, intrigue, and various other mischiefs, proceed, that totally counteract the good intentions of the donors, injure much and endanger the happiness, comfort and safety of the patients. In many instances, the properties of the charity are prostituted to the worst of purposes, as proved by the investigation undertaken, but greatly to the dishonour of that erratic and eccentric nobleman, Lord Brougham, never completed. Situations are created with enormous salaries for the relatives, dependents, and friends of the governors, the offices of surgeons and physicians, whose competency is the least thing considered, are decided by ties of consanguinity, and affinity; all are, and have been, nice snug family or matrimonial arrangements. Sons and cousins, daughters, nephews, nieces, and the most distant ramifications of the genealogical tree are provided for, as will be seen in the history of the several individuals we are about to sketch, connected with the hospitals of Thomas and Guys. As may be expected, some of those introduced by these illegitimate means are clever men, others have not the slightest pretensions to the character. Talents and knowledge are not transmitted from father to son, they are personal, they are born and die with the individual.

The sons of the greatest men have been the greatest fools. It is natural that the son should inherit the property of the father. It is not just nor natural that he should usurp the privilege of experimentalizing and tampering with the lives of the poor. This system, by its workings, is not merely injurious to science and to deserving merit, but it is cruel, and even murderous in some instances, to that class of society which should have our sympathies, and which cannot befriend or protect themselves. In no hospital in London has nepotism been so offensively powerful as in Guy's and St. Thomas's. All the situations descend in lineal succession in two or three families, who have monopolized them for nearly a century. The exceptions are *rare*, and in favour of an occasional intruder whom aldermanic influence or champagne dinners have introduced.

The principal surgeon of St. Thomas's is Joseph Henry Green, F.R.S., Professor of Anatomy to the Royal Academy, &c. &c. He is the nephew of the celebrated Cline, and one of the Council of the College of Surgeons. He was associated with Sir Astley Cooper in his Lectures on Surgery and Anatomy, and took the place of Henry Cline, a promising young surgeon, who died in early life. He is of a very tall, commanding figure, being fully six feet in heighth; he is beginning, by years and the gout, to incline a little forwards from the perpendicular, and his clothes begin to hang rather loose upon him. His features are regular and pleasing in detail, and are expressive, in the aggregate, of intellectual power. His countenance is placid and amiable, slightly indented with the effects of small-pox; hair, light and sandy; chin, rather long and edentulous. On the whole, there is an ease, an elegance, a state of dignified repose, that harmonizes with the character of the finished gentleman and accomplished scholar, which is generally accorded him. He goes round the wards three times a-week. He is courteous to all, now and then, when not wrapped up in his reflections upon the inflections of Greek verbs, or in his dreamy idealities, or German metaphysical speculations, he is *communicative*. The mind, in him, is deeply fraught with classical literature; it seems to be interwoven with the very fibres of his understanding. The display of learning in him is natural and irresistible. It is not pedantry, or a desire to astonish by his acquirements. He thinks aloud in the dead languages.

The other day he ordered a man, who had injured his spine, to walk across the room. The patient complained he could not feel his feet; he made a quotation from Homer, describing him as "treading on air." One of the students *naively* asked another, if he would find a description of that disease in Cooper. Of the merits of this gentleman there are the most conflicting opinions. Some of his pupils contend that he is the first operator, the most eloquent professor, the most skilful surgeon in the metropolis, and

"They would draw
A faultless monster, which the world ne'er saw."

Others, less prepossessed, subtract too largely from these superlative panegyrics, and depreciate his merits overmuch.

We will recite his chief professional performances, so that every reader may place himself in the judgment-seat, and award the amount of claim he has upon his *brethren*.

In the session of 1821, he delivered the introductory to a course of lectures, in which his opinions recently expressed and advocated, are advanced with the same arguments, illustrations, and quotations, as in his pamphlet on medical reform. This lecture possesses all the freshness and integrity of an original thinker. It has none of the florid and figurative embellishments that detract from his more matured and polished productions. There are none of those narratorial interruptions of undisguised plagiarisms which mark the clumsy compilations of some of his cotemporaries. He thinks for himself in a healthy tone, and in a way peculiarly his own. His refinements are in the matter, not in the language of his discourse.

As a practical surgeon, we find that in 1827, he operated on forty cases of lithotomy, and lost only one. This success created a great sensation at the time, as it is unequalled in any country, and in any other person's hand.—Mr. Martineau, of Norwich, the most successful of all, out of eighty-four lost two. Mr. G. uniformly uses Cline's gorget.

In 1830 he was appointed to the professorship of surgery in King's College. At the commencement of his career, he suffered under a formality and mannerism which he could not shake off. On the opening of the session no man could be more eloquent in his address; his deportment simple, chaste, refined, dignified, and most successful in impressing his principles and points of practice on his class. It was much admired; it was delivered in a most masterly and effective style. It began with a lucid exposition of the connection and relation between the three great professions, law, physic, and divinity, the common root of which he proved to be science. The law, he contended, preceded the others, as, in its extended sense, it includes both the legislation and the administration of the laws. —He took an historical retrospect of the monarchy of Egypt, the priesthood, its practices, Moses, Hebrew laws of morality and Hygiene, the science of moral obligation, the Levites government of medicine; then a review of the laws of Minos, Solon, and Lycurgus, the Theodosian code, Christianity, its metaphysics and ethics, the scholastic age, separation of divinity and physic, the causes, the reformation—when astrology had faded away before the dawn of true astronomy, and the last dreams of alchymy, in the ascending light of chemistry,—Harvey and his discovery, Stahl, Boerhave, Hoffman's iatro-chemical school, how John Hunter laid the grounds of harmonizing the distinctions, shewing that life, or the principle of vitality, is the activity of function displayed through organization—that this vital principle is necessarily in order, antecedent to organization; and its essential condition; and how he placed the

seal on his great labours by including the human anatomy in the science of comparative or universal anatomy, and the lecturer concluded in a glowing and enthusiastic eulogium upon the merits and benefits to science of this truly great man, and on the pleasures, delights, and glories of ancient literature and its alumni, Oxford and Cambridge.

This was the most brilliant lecture he ever delivered. In 1831 he wrote a pamphlet called, "Distinction without Separation," addressed to the president of the College of Surgeons; the inference from which, we presume, is, that he means the distinctions between physicians and surgeons do not really exist, and that the present division is highly injurious. He defends the college, and denounces the general practitioner: and a little further on he declares the former must be reformed, and that the latter have just cause of complaint.

About this time he entered into a wordy warfare with the medical press about the publication of his lectures, in which he was severely handled and totally discomfited. He published a dissector's manual, which is never read.

In his evidence before the parliamentary committee, he declared the whole of the evils of the profession were in the student's education. He would make the council self-elective; although it has caused some dissatisfaction, he declared there was no ground for it. He does not approve of Concours. The distinction between surgeon and physician he considers highly beneficial. He is averse to the *representative* principle which governs every other associated body in the kingdom except ours. He gave no reasons for this opinion, and frequently contradicted himself. It is a tissue of nonsense, absurdity, illiberality, and illogical reasoning. In his "Touchstone of Medical Reform," he abolishes the Apothecaries' Hall. He gives the requirements necessary for a general practitioner. He pitches the standard very high; one of which, that he *must be a gentleman*,—and yet to this imaginary being, he denies the principle of self-government, and gives it to a class of beings called *pures*, on the principle of *lucus a non lucendo*, who are daily invading the boundaries of every branch of medicine, and pretend to practice surgery exclusively.

In a letter to the *Times*, 1834, headed "Suggestions respecting an Intended Plan of Medical Reform," full of strange, far-fetched, quaint language and fantastic distinctions, in which, here and there, are to be found a few grains of sense in a bushel of chaff; he enters into a long category of qualifications, and that the pupil should have a sound classical and mathematical education, in which we agree with him, as we hold that the member of a liberal profession should have a liberal education. He concludes with the monstrous proposition of higher and lower grades, under very long and unintelligible names.

His style through the pamphlets and suggestions, are fine specimens of the transcendental; he is radical now and then in his theory, but rigidly restricted and narrow-minded in his practice: his better judgment seems to be obfuscated by the gross atmosphere of selfishness in which he lives, moves and has his being. In 1840 he delivered the Hunterian oration. After a very extraordinary and allegorical exordium, he, in his own metaphysical way, endeavoured to explain the idea which occurred to John Hunter's mind. Preparatory to this, he entered into an elaborate elucidation of the metaphysical notions entertained by the deservedly celebrated Coleridge, his intimate friend and congenial spirit; whose wild and visionary—nay, poetical and subtle notions, are intended to subvert the Utilitarian speultaions, prevalent in the present day. He rendered it most enrapturingly mysterious and incomprehensible, by employing abstract metaphysical terms in a sense different rom their accepted significations, and by coining several new words, and by the profuse employment of metaphors, Greek and Latin quotations, praises of Coleman, Cline, and Cooper, and whole pages from the mysticism and periodical works of Coleridge, noumenon in contra-distinction to phenomenon, Coleridge's notions of church and state—this lecture he called on vital dynamics. He says truly, the forming of an hypothesis precedes the inductive process. In the aptitude to form theorems consists the force of what is called the inventive powers. Dalton possessed the faculty when he bodied forth the doctrine of definite proportions. The inventive genius of Faraday and Oerstad struck out the idea of a new dynamic principle: this lecture is published; we confess we derived neither pleasure nor instruction from its perusal. Common sense is overwhelmed with learned research, with the weight and length of words, with the number of quotations, with metaphors borrowed from Coleridge, with metaphysical speculations quite irrelative to the subject. He was obliged to write an appendix to interpret the lecture, and to deliver a recapitulatory lecture to explain the appendix.

His opening oration at the new school of Thomas, this session, was well attended. The style was more subdued and sensible than the Hunterian oration, more adapted to his audience. The science and art of the profession, its progress—astrology to astronomy, what empiricism is to medicine—their analogues—the intellectual chaos, and bewilderment of the one, yielding to the reflective rationale of the other: then a review of the Ptolemean with the Newtonian system—Kepler's anticipation of the sublime geometry of Newton, and here the lecturer careered in the clouds, and used the fact as an illustration of the perfection of art or science. Then electricity afforded him space to launch into its wonders, its mysteries. Amidst this learned rhapsody, there were noble views beautifully expressed. The orthoepy of his Greek quotations was music to our ears, accustomed to hear that fine language murdered by animals who try to make the world believe they understand, when they are ignorant of the accent, uses, power, and pronunciation of its alphabet. In this, as in all his discourses, we had the old sophism, *cum hoc propter hoc*. The anecdote of Louis XIV, and the quack, quotations from Bacon, were given, and it ended with an eloquent denunciation of all species of empiricism. It was much applauded.

When we reflect on his great opportunities, and contrast them with the little he has done to record its results, a singular contradiction arises, and a comparison with other men is the result. We are told he possesses genius—the essence of his own vital dynamics. We know he has had extensive practice—has he added to the boundaries of science or to operative surgery? His setons in hydrocele are not original. The test of genius he lays down, himself, is to create, to discover, to improve, what is already known.

He has great and extensive merits; they are, too, of the highest order,—they are not of a practical character. Yet he is a splendid surgeon and operator. We mean, he has not that great attribute that immortalizes the possessor, and draws the line between great genius and pre-eminent talent. His lore is profound,—his whole career a glory to his profession. Personal property has placed him above professional competition. He lives in Hadley, and is universally esteemed. He has troops of friends and admirers. With Horace, we pray, "*Ut serus in cœlum redeat.*"

PROBE.

THE MEDICAL CORONER.

To the Editor of the 'MEDICAL TIMES.'

SIR,—In your valuable and widely-circulated journal of November 12th, you have, under the heading of "*Cheapness of Medical Coroners*," clearly shewn to the hitherto-duped Profession what a very disinterested friend they have in the self-elected champion of Medical Reform. Your remarks at the above period were wonderfully *apropos*, but "coming events often cast their shadows before." Covetousness after this world's lucre seems to be, in some, more consuming and unquenchable than * * * In your Journal of December 10th, you have again reminded the Profession of their rights, by publishing some important clauses from the Act regulating the "payment of medical witnesses at Coroners' Inquests."—"The Coroner is empowered to summon on an inquest the legally-qualified practitioner who attended the deceased at his death, or during his last illness."—" Or, if deceased was not so attended, to summon any legally-qualified practitioner 'being in actual practice in or near the place where death happened.'" Now, Mr. Editor, is the Coroner guilty of any breach of the Act, if he, knowing the patient has been attended, till within two days of his death by a respectable man, summons another medical gentleman upon the inquest, who knows nothing of the case? Does such a plan of proceeding not necessarily incur a *post mortem*, and, consequently, unnecessary expense upon the county? Next week, if you will afford me space, I shall furnish you and the Profession with such facts as will open their eyes, if not hermetically sealed—facts that will arouse just indignation in the heart of every honourable member of society. I will further assist you in shewing the Profession how they are fleeced of their just rights, and their hard-earned character calumniated by our M.P., the IMMACULATE HYENA. A tale shall be brought to light, of which others, more deeply interested than the writer, seem unfortunately to be totally ignorant. I only wait to see what this week discloses!

Yours always,
NO GULL, TOM PEACHUM.

Dec 14th, 1842.

[If any charge be made against Mr. Wakley's discretion, or honesty in the discharge of his magisterial duties, our informant must communicate his name in confidence to us. The moral presumption may be very strong, in particular cases, of the truth of a correspondent's charges—but, where character is in question, we prefer to approach certainty as nearly as possible.—ED.]

REFLECTIONS ON THE "TRUE AND FALSE" STUDY OF BOTANY.

(From a Correspondent.)

A FEW remarks on the present mode of studying botany, and the cause of its being productive of so little real benefit may here be not uninteresting to the reader. Being in medical practice myself, and having paid great attention (as I still continue to do) to the delightfully agreeable and simple study of botany, and to the modes of advancing the utility of this science adopted by professors both at home and abroad, a few remarks on the ordinary, unprofitable, and what I consider the really beneficial mode of attempting to answer the sought for ends of this occupation will I hope not be considered as an attempt to deny the advantages of botany, but to change the ordinary mode of studying it, from what it is, i.e., that of drying, collecting, arranging and unarranging plants, to the really proper mode of considering plants in their natural relation to inanimate and animal matter, as beings that are placed between the two for the sole use of animals. Many persons, and some of good fame, have denied the utility of this study; and I must say, considering the number of years, and good men who have engaged in it, the results are comparatively nugatory. I must not be misunderstood here in saying that, the results have been nugatory: I mean to say that beyond the mere conveniences of reference and description, botany has been silent in its productions. The real utility of this science consists not in merely affording pleasure to those engaged in its pursuit, but by its ends affording results which can be advantageously applied to the comforts and happiness of human life. But advantages of this sort, notwithstanding the enormous accumulation of botanical knowledge, have never yet appeared: the important uses of many vegetables would never at this time have come to light, had it not been for what I may call "botanical quacks," i.e., persons studying the culture of vegetables in the same manner as quacks study medicine. Let us examine the occupations of the most eminent botanists, and also those of the most eminent farmers and gardeners (botanical quacks.) The former are almost exclusively engaged in compiling large ponderous volumes of the external characters of plants, sometimes but rarely diving into the interior; the foreign authors have, however, done considerably more than our home writers. Well, then, here we have men devoting their whole lives to the external characters of plants, arranging them, comparing their externals, collecting and preserving them. The farmers

and gardeners are occupied in just the reverse, leaving all structure both external and internal, they devote themselves entirely to the culture or growth of vegetables, all their facts being obtained by pure experience, and are not attempted to be explained. We have here no interveners, no men who are engaged in scientific investigations and on practice also. Has the knowledge of animal anatomy and physiology been thus advanced? Certainly not. No organs in animals (whose external characters are almost omitted in the study of these beings) are viewed without a consideration of their corresponding functions; but in the study of botany the functions are comparatively never considered. We can see and readily understand the use of four stomachs in a gramniverous animal, and of only one in the carnivora, but the use of the internal vegetable organs we are almost entirely ignorant of. All their varieties, and which we must suppose not to be without their use, are in a physiological view perfectly unknown. Has our knowledge of the functions and structure of the lower animals and ourselves been advanced solely or almost exclusively by the arrangement into artificial or natural systems? No! But to this point, nearly all our botanical labours are directed. In plants, as explained above, we have not the anatomist and physiologist at work together, but each separately and in his own way. Comparative or human anatomy is never considered (or rarely) apart from function. We have thus learned the use of various structures in performing functions, both relating to the constituents of the body itself and the surrounding influences and agencies to which it is exposed. Also by experiments we have been able to ascertain the effects exclusively of different atmospheres, diet, medical agents, &c., as well as such varieties of these means as will produce effects almost at our own disposal. Thus we can repress or increase the growth of certain parts, render the body exposable without injury to otherwise noxious agents, obviate their effects when taken, &c. But what real benefit (save convenience of reference or communication) could physiology or anatomy receive from the most complete or even perfect arrangement of animals. But this (in botany) is what is occupying, or rather wasting, the time of most of our scientific men. The gardeners and farmers laugh at them, and tell them they will produce fine crops of corn and vegetables without any of their "theory." The true use of botany, so as to be of utility to mankind, must be in a somewhat similar one to that which has advanced anatomy. We must leave the classifications, to devote time to find out the use of the different organs, their growth, &c. The "quack" botanist can and does continue to improve the culture of vegetables, so as to render those naturally poisonous, not only not injurious, but actually beneficial and conducive to health. How this is effected he knows not, nor does he care. The botanist should know the tissue in which the noxious principles are placed; and the sources whence they are derived, or at least the causes of their production. But does he? No. He knows nought but what the gardeners have found out by experience. As it is at present, botany is little else than sheer waste of time; and all the arrangements of plants according to what are called *natural or artificial systems*, must be looked upon as merely conveniences, whereas they now occupy the sole attention of botanists. Any person not wedded by vile prejudice to the ordinary views, must be aware that every year new plants are being found, which cannot be referred to any now existing "natural order," and, therefore, unless we had the characters of all the plants on the earth, we could not say whether any unknown one was poisonous or not. To distinguish a harmless from a poisonous plant has been considered as one use of botany to medical men; but the fallacy of such an use has been explained above. Moreover, the cases in which this could benefit, i.e., to people who are in unknown countries, or in those whose botany is unknown, are very rare. Whereas in the largest and most populous cities the selection of poisonous plants for medical use (and those too virulently so), is entrusted to the hands of a gardener or chemist, totally unacquainted with botany in any sense of the word. I hope these remarks will have a tendancy to the following ends:—

1. To persuade those botanists, who have time and means, to do as Liebig has commenced; (but which even with that celebrated philosopher will never answer its full ends, he not being a good botanist) viz., to connect plants with external influences, on the varieties of which we have reason to believe their properties solely depend.

2. To provide competent persons to select plants for medical use.

3. To employ botanical talent to other and more valuable ends than the drying and collecting plants, making natural orders one day and altering them the next.

4. To lay before the medical examiners the propriety of requiring of medical students some knowledge of sound philosophical botany; and leaving all the natural system humbug, which always has been, and always will be, varied by every author's whim and fancy.

I hope, and earnestly look to the time, for something like the advancement of real botany. The long continuance of the old method of examining the external characters merely, and thus judging of or totally neglecting the interior (on whose variations the exterior is totally dependant), has advanced nothing more than the mere making long lists and then altering them.

Hernia Diaphragmatis congenita, and an attempt to explain its manner of arising, by Dr. Scholler.—11 The saline bath, Elmen, near Salze, in the circle of Magdeburg, in the year 1840-1, by Dr. Lohmeier, Bath Physician of that place.—12. The Orthopœdic Institute of Paris, with especial reference to Orthopœdia in its present point of view.—13. Miscellaneous.

*** The German works above announced, may be had through Mr. Alexander Black, 8, Wellington-street, North.

PERISCOPE OF THE WEEK.

LOCAL TREATMENT OF CHANCRES BY SULPHATE OF COPPER AND CYANURET OF MERCURY.—Dr. Strohl recommends the sores to be dressed five or six times a day with charpie, which has been soaked in a solution of about a grain and a half of sulphate of copper, to an ounce of water. Simple chancres when thus treated, usually heal within twelve days. Dr. Strohl assures us that he cures complicated chancres in an equally short time with an ointment composed of two grains of cyanuret of mercury to an ounce of axunge. This ointment is spread upon a piece of linen corresponding to the size of the sore; it is apt to be painful at first, and must occasionally be removed after it has been on for an hour or two, and the remedy must be applied in a weaker form. When the chancre is extensive and painful, after the ointment has been on from four to ten hours, according to the sensibility of the patient, it is dressed with mercurial ointment, or opium cerate.

SUPERACETATE OF SODA IN THE WRAPPINGS OF A MUMMY.—On moistening, says Dr. H. Johnson, in the *Chemical Gazette*, a portion of mummy-cloth with distilled water and applying litmus paper, the latter became reddened, proving the presence of a free acid: the same effect was observed in several different portions of the material. I desired, therefore, to know what was the nature of the acid.—*a.* Some of the mummy-cloth was infused in cold distilled water; the liquor reddened litmus, and effervesced with bicarbonate of potass; evaporated to an extract and mixed with strong sulphuric acid, it yielded fumes which were recognised as *acetic pyroligneous acid* by the smell.—*b.* A portion of the liquor (*a.*) was distilled in glass vessels. A transparent, feebly-acid liquor came over, which, being free from the vegeto-animal matters dissolved by the water, seemed to afford the usual reactions of acetic acid.—It gave no precipitate with solution of acetate of lead, muriate of baryta, or nitrate of silver (except when concentrated, in which case it was crystalline),—The liquid remaining in the retort was more strongly acid than what came over in distillation; it contained much animal or vegetable matter, imparting to it a high colour. It was saturated with bicarbonate of potass and then evaporated to an extract; and on adding sulphuric acid, the pungent and characteristic vapours of acetic acid were distinctly perceived. The acid here present could therefore be none but the acetic.* On referring to Mr. Pettigrew's work (p. 76), I find that M. Rouelle obtained an acid liquor by distilling the bituminous matter contained in a mummy. He does not state what was the nature of this acid; and, it may be remarked, that as obtained by him, in the destructive distillation of these substances, the acid and oil which he describes as coming over were probably not contained in the materials of the mummy, but were *produced* in the process. They were *products*, not *educts*, of the distillation. Mr. Pettigrew (p. 62) conjectures that a considerable heat was employed in the making of mummies; and M.

* See Parnell's Elements of Chemical Analysis, pp. 46, 47.

Rouyer, whom he quotes, supposes that the bodies must have been put into stoves in order to bring about a union of the resinous and animal matters. What Mr. Pettigrew and M. Rouyer conjecture we may now, I think, positively assert:—1, because the mummy recently opened here (in Shrewsbury) by Mr. Birch had evidently been quite charred; and of this a piece of the bandage now before me affords visible and indubitable evidence; 2, the presence of acetic or pyroligneous acid in the wrappings is another proof of the fact. The charred state of the wrappings proves that after their application the body has been subjected to a heat equal at least to 300 deg. F. This temperature would decompose a part of the pitch and resinous substances, and produce a quantity of acetic or pyroligneous acid besides other matters, such as empyreumatic oil and creosote. The utility of this operation is quite obvious: it would not only cause the bitumen and resin to melt and combine with the animal matter of the corpse, but the abundant escape of pyroligneous acid, creosote, &c., and the impregnation of the whole mummy and its wrappings with this would greatly tend to preserve the body from decay. Hence it appears that mummies were prepared or "*cured*" much in the same way that Westphalia and other hams are at the present day; namely, by pyroligneous acid; and, as suggested by Mr. Cormack, by creosote.*—The peculiar yellow colour of the bandages I have no doubt is produced in the operation of "smoking" the mummy, and arises from the empyreumatic, oily, and some extractive matter dissolved by the acetic acid as it is evolved. The colouring matter is soluble in water and in alcohol, and seems therefore to resemble extractive matter of chemists. Solution of persulphate of iron deepens the colour but does not render it black; hence it cannot be astringent matter. Herodotus tells us the body of the mummy was covered with nitre of natron, *i. e.* native carbonate of soda. The truth of his statement is borne out by the crystals collected and analysed by Dr. Grenville, and the examination of a saline matter discovered by Dr. Ure. Saline particles were also discovered in the opening of the mummy here (in Shrewsbury), but unfortunately they have been lost.—If the account given by Herodotus be true, that the body was covered with carbonate of soda, and as I have endeavoured to show, acetic acid would be produced and given out in the process of embalming, the carbonate of soda would be converted into acetate, or from the excess of acid into the superacetate of soda; and that this has happened I have proved to my own satisfaction by the following experiments: Some of the wrappings were digested for an hour in distilled water. The liquor was evaporated to dryness. When much concentrated it was found decidedly acid. The solid extract weighing 7 grs., was heated to redness, and thus reduced to a white ash mixed with some charcoal. The ash effervesced with muriatic acid; it dissolved in water, and the solution rendered turmeric paper brown, and restored the blue of litmus reddened by an acid. Evaporated to dryness, it left a white crust, not deliquescent, but soluble in water. The solution exhaled bubbles of carbonic acid on the addition of a drop of pure muriatic acid; and this solution gave no precipitate with solution of muriate of platinum. It was, therefore, carbonate of soda, and no doubt some of the natron, which had been used in the preparation of this mummy more than 2000 years ago. It remains for others to verify these results by similar experiments on other mummies.

* According to Mr. J. R. Cormack (Treatise on Creosote, 1836), the only essential part of the mummifying process practised by the Egyptians was the application of such a heat as would dry up the body, and then decompose the tanny matters which had been previously introduced, and thus generate creosote.—Pereira, *Mat. Med.*, Part I. p. 227.

Observations on Copaiva Balsam.—Copaiva balsam, says, M. Vigne, is derived from Columbia, Brazil, Peru, Cayenne, and the Antilles. None appears to come from Mexico. The best is that imported from Maracaibo and St. Martha, which is packed in oak casks containing from 1 to 1½ cwt., in large bottles, or in cylindrical tin boxes. The boxes contain about 6 kilogrammes, are closed at both ends by flat soldered lids, and the one lid has an aperture in the centre, which is closed by a square piece of tin-plate soldered on. This mode of packing renders all adulterations very difficult (excepting naturally such additions as are made when it is collected, for instance chalk, to saturate the free acid,) but the balsam seems to change very much in these boxes. The author examined samples from 12 boxes obtained at the same time and from the same locality; but not one agreed with the other, not one was entirely soluble in alcohol, and smell, taste and consistence were different in all. In those boxes from which the balsam flowed out, *clear* crystals were deposited, which were obtained perfectly white by means of bibulous paper; but no such sediment was found in the opaque balsam; this did not clarify even on being left to stand, but when kept in a moderately warm place deposited a resinous substance quite distinct from the crystals. The clear balsam dissolved nearly wholly in alcohol, the opaque always less, sometimes scarcely at all. The most opaque and least soluble in alcohol did not even clarify on being treated with ammonia, while all the others formed with it a clear solution. The crystallized resin dissolved abundantly in hot alcohol, but separated almost entirely on cooling: the solution had an acid reaction; while, on the other hand, neither the balsam nor the resin which had separated from it possessed acid properties.—The author further examined 12 different samples from St. Martha, which had been imported in oak casks. They were likewise all different, although in general more transparent and thicker than the former. The following experiments were made with the best, perfectly transparent, amber yellow, aromatic smelling, samples of the consistence of turpentine.—With 1-20th *magnesia usta* it became in 24 hours like a thick gum slime; after 48 hours it was considerably thicker, and subsequently acquired a good pill consistence. It did not dissolve in an equal part of alcohol of 0.914, but afforded a milky mixture, which soon separated into two layers, of which the upper one contained but a little copaiva. Alcohol of 0.900 dissolved it in every proportion at 59 deg. F. A mixture of 2½ balsam and 1 ammonia soon became transparent, and might be heated to 212 deg Fahr. for half an hour without any change taking place. On boiling it with 50 times its weight of water the balsam lost half its weight in æthereal oil. With caustic potash it afforded a kind of emulsion, upon which the saponified balsam soon swam.—Only one of the other samples gave a good mass for pills with 1-20th magnesia; two became somewhat more consistent, but not sufficiently so; three became thick at first, but subsequently liquid again; and four did not change at all, but deposited the magnesia. The second sample afforded with ammonia a clear constant compound, with the two next the combination was less constant; the fifth and sixth only became clear after some time; the others remained opaque. Not one sample dissolved entirely in alcohol of sp. gr. 0.914; the more pure in every proportion in alcohol of 0.900; the last sample, even with this, separated into two layers. The loss in æthereal oil was about the same in all the samples, but the last lost 70 per cent. instead of 50. It is evident therefore that the power of dissolving in alcohol, of becoming consistent with magnesia, and of entering into a constant combination with ammonia, are nearly parallel; but these properties evidently depend on the amount of acid resin, and the thicker balsams therefore exhibit them in a greater degree.—The last sample, which had a very agreeable smell, and was very liquid, nearly colourless, perfectly transparent, and stated to be from Para, contained evidently more æthereal oil and less resin than the others, and on account of its imperfect solubility in alcohol was considered to have been adulterated with a fat oil; but the residue from the distillation was dry, and that was consequently out of the question. When kept for a long time in a badly stoppered bottle it became gradually coloured, and more soluble in ammonia and in alcohol, evidently from more of the oil being converted into resin.—The author further examined two samples of balsam from Para, which were considered to have been purposely adulterated with rancid oil of almonds. They dissolved well in alcohol, but combined badly with magnesia and ammonia. Direct experiments showed that pure copaiva balsam may be adulterated with 50 per cent. of a fat oil (nut oil, almond oil), without its ceasing to give a clear solution in 2 parts alcohol. Only after from 12 to 15 hours does the oil separate. Excess of alcohol separates the oil in all cases. It is evident therefore that under certain circumstances an unadulterated balsam may be insoluble or of difficult solution in alcohol; an adulterated one, on the contrary, may be soluble. The best test for detecting the fat oils would be alcohol to which some caustic potash has been added.

Anomalous Suppuration of the Cerebro-spinal Membranes.—Jacob Eichinger, a soldier in the 4th Light Infantry Regiment, had enjoyed good health during the seven years that he had been in the service. On the 17th of November, 1839 he was suddenly attacked with symptoms of gastric derangement, which increased on the following day, and compelled him to go to bed at about a quarter to twelve, a.m. He fell asleep, and awoke in an hour delirious. Convulsions soon supervened; the man became comatose, and, although the most active antiphlogistic treatment was had recourse to he died on the following day, November 19th, at half-past four in the morning. The body was examined on the 20th. The cranial bones were remarkably thin and the right side of the skull somewhat prominent. The whole of the superior surface of the cerebral hemispheres was covered with a layer of yellow fluid pus, and appeared somewhat flattened; no trace of the arachnoid could be found at this part. The pia mater was highly congested, and infiltrated with pus in its prolongations between the convolutions; the substance of the hemispheres was very much softened, and contained numerous points of blood when cut through; the lateral ventricles empty, and their walls softened in the highest degree; the pineal gland was very much enlarged, and did not contain any calcareous matter. The inferior surface of the cerebrum, and the whole of the cerebellum, were covered with pus, and extremely soft; the arachnoid here also appeared to have been destroyed; the base of the cranium was bathed in pus; no fluid in the third or fourth ventricles; the pineal gland much injected. The inner surface of the trachea was of a light red colour, but the bronchi were healthy. There

were some adhesions between the pleuræ, and the substance of the lungs was much congested, a few tubercles in the upper part of the left lung. The heart was very large, soft, and loaded with fat, but not diseased. In the abdominal cavity nothing worthy of notice was found. The bladder contained about half a pint of turbid urine. The fibrous membrane of the spinal marrow was much injected, and the cellular membrane particularly so; its whole surface, and especially opposite the cauda equina, was bathed in the same kind of purulent matter as the brain; there was no trace of the serous membrane, and the substance of the spinal marrow itself was converted into a thin, pultaceous matter.—This remarkable case is unique in the annals of medical science. Pathologists must decide whether the inflammation commenced in the arachnoid membrane, or extended to it from the softened nervous tissue, or whether both states were simultaneously produced by one and the same cause. But, however this may be, we cannot but be struck with surprise that such extensive softening of the cerebro-spinal nervous mass, and universal suppuration of its serous membrane, should have existed without the production of any symptoms to indicate such extensive disease. Particular inquiries were made in the regiment in which the man had served, and it was ascertained that during the seven previous years he had enjoyed excellent health, having continued to do his duty as a soldier without interruption. It was only two days before his decease, that gastric and convulsive symptoms made their appearance, and quickly terminated in coma and death.

The Taliocotian Operation Novelly Applied.—Miss A. T., at the age of five, was severely burnt. The result was an exceeding degree of deformity. The lady in describing her condition, says, "I have been unable to throw my head to my left side, or backwards, or to close my mouth for more than a few seconds at a time for twenty-three years. My right eye was drawn down some distance below the other, and when I endeavoured to turn my head it was entirely closed." Dr. Mutter, of Philadelphia, on examination, found in addition, the angles of the lower jaws altered and the incisor teeth nearly horizontal (as is seen in cases of chronic hypertrophy of the tongue) by the pressure of the tongue, which organ, in consequence of the inability of the patient to close the mouth, was always visible, and indeed, protruded when she was silent. The clavicle of the right side was so completely imbedded in the cicatrix, that it could scarcely be felt, and there was not any external indication of its location. The chin, from the shortness of the band, was drawn down to within one inch and a half of the top of the sternum, and the head consequently inclined very much. The space between the chin and sternum was filled up by the cicatrix, so that no depression existed in front of her neck. The ordinary operations in such a case not offering any chance of success, Dr. Mütter decided on practising a novel application of the process of Taliotius, which he accordingly executed on the 12th. January, 1841, assisted by Drs. Noble and Pierce. The steps of the operation were as follows; the patient being placed in a strong light, and seated on a low chair, her head was thrown back as far as possible, and sustained in this position by an assistant. The operator then, seating himself in front, began by making an incision which commenced on the outside of the cicatrix in the sound skin, and passed across the throat into sound skin on the opposite side; this penetrated merely through the integuments, and was made as near the centre of the cicatrix as possible. It was, therefore, about three quarters of an inch above the top of the sternum and of course in the most vital part of the neck. The object in making it so low was to get at the attachments of the sterno-cleido-mastoid muscles, which, in consequence of the long flexion of the head, were not more than three inches in length, and required on one side complete, and on the other partial, division before the head could be raised. The integuments having been thus divided, the cicatrix was next carefully dissected through, until the fascia superficialis colli was reached, and then the right sterno cleido-mastoid was exposed, and both its attachments divided on the director. The head could then be raised an inch or two, and when the sternal attachment of the left sterno-cleido-mastoid was divided, the head could at once be placed in its proper position, the clavicular attachment of the muscle offering little or no resistance. A wound, six inches in length by five and a half in width, was thus made, and yet there was scarcely any hæmorrhage, only three or four vessels requiring ligature. To fill up this immense chasm, an oval flap, six inches and a half in length by six in width, was dissected from the left shoulder, its attachment to the upper part of the neck being left intact. This dissection was painful, but not bloody, only one small vessel being opened. The flap, thus detached, was next brought round by making a half turn on its pedicle, placed in the gap it was destined to fill, and carefully attached by several twisted sutures to the edges of the wound. It was also supported by strips of plaster. The edges of the wound on the shoulder from which the flap had been removed, were next brought together by straps and sutures, and with the exception of its upper third, carefully covered in. A pledget of lint, moistened with warm water, was next laid upon this raw surface, a bandage applied by which the head was carried backwards and maintained in this position, and the patient put to bed. This very severe operation was borne with the greatest fortitude. Very little disturbance followed; no unfavourable symptom made its appearance, and union by the first intention took place throughout the entire wound, with the exception of one small point which united by granulation. The wound in the shoulder, except just over the acromion process, also healed kindly and the patient has been relieved of nearly all inconvenience. The angles of the lower jaw have, in consequence of the change in the condition of the throat, regained in a great measure their proper shape, and the lower incisor teeth have been straightened and one of them extracted by a dentist To support the neck after the incision had healed, the patient wore a stiff stock for a while by Dr. Mutter's directions, and this instrument served to press the integuments back, by which the natural excavation or depth of the neck in front was readily effected. The motions of the head are perfect.

Malignant Diseases of the Skin.—Dr. Byron, of the Meath Infirmary, gives a detail of his experience in the use of the chlorate of zinc as an escharotic. His paper refers chiefly to the treatment of lupus exodens, affecting the nose, eyelids and cheek. In the first case, that of a man, forty years of age, the lupus commenced about six years previously, and at the time of his admission, there was a superficial ulcer not apparently deeper than the cutis vera, occupying upwards of two thirds of the right under eyelid, extending from near the outer commissure along the tarsal border, which, with the cilia, was removed to the extent mentioned, leaving the globe of the eye and its conjunctiva exposed; the latter was thickened and drawn inwards, and the inferior margin of the ulcer was irregular, not materially thickened nor everted, but excavated, presenting much the appearance of herpes rodens, and its surface pencilled over with a thin pale gelatinous matter, which, though soft, was not easily removed. There was a painful sense of heat and itchiness in the ulcer, which, however, seldom amounted to absolute pain, but he suffered at times from pain in the head of a lancinating nature. His general appearance was indicative of disorder, and his spirits were depressed, but there were not any appreciable indications of physical disease, or functional disturbance.—The entire surface of the sore was touched with the chlorate of zinc, by which the sensations of heat, pain, &c., were in a great degree removed. The pain of the application was excessive, and the heat and redness caused by it continued for two days. When the inflammatory symptoms had subsided, the application was renewed, but only to the margins and foul parts of the ulcer, by which it was much cleaned, and healthy florid granulations induced. The chlorate was applied every third day to those parts only which presented a foul or unhealthy appearance, and never until the heat and redness consequent upon the preceding application had gone off, and at the end of a month cicatrisation was completed. The chlorate of zinc was used ten times. The rapidity with which the aspect of these ulcerations is improved under the use of the chlorate of zinc is, Dr. Byron considers, at once a proof of the efficacy of the remedy, and also the local character of the affection up to a certain period. What that period is, when all known remedies prove useless, remains to be ascertained. He uses the chlorate in the solid form, although it has hitherto been advised to be applied either in solution or in the form of a paste made with lime, flour, or some such substance, because—1st, it is at once, and in the full enjoyment of its escharotic powers, brought in immediate contact with the diseased surface; 2d, its reapplication is regulated by existing circumstances; and 3d, no parts are subjected to its use but those which seem to require it. Some precaution is necessary in the application of this powerful escharotic to the skin of the head and face in young subjects; for them it should be diluted by the admixture of from three to ten parts of water, and the pain, redness, &c., consequent on one application, should always be allowed to subside before it is reapplied, else a slough of the part will probably follow. The same precaution is not necessary to the same extent with persons advanced in life. The following are the inferences drawn from the cases detailed in Dr. Byron's communication.—1st. Malignant ulcer of the eyelid is, in its earlier stages, up to a period not yet defined, local, and admits of cure by local treatment only. 2nd. It is usually a disease of advanced life, but is not confined to any temperament or condition of life. 3rd. This malady is rarely found combined or coexistent with other affections; on the contrary, its presence seems to exempt from any such liability. The sympathetic affection of the stomach, bowels, bronchi, already referred to, forms an exception to this rule. 4th. Lupus, on the contrary, seems in most instances to have a constitutional origin, being as already shown, found to follow from or coexist with other affections or disordered conditions of the system, moreover, it is most effectually checked by constitutional, combined with local treatment. 5th. The difference, through well marked in several instances, between these two affections is infinitely less apparent than between either of them and cancer. 6th. The term "malignant" may be fairly questioned, as being applicable to the earlier stages of ulcers of the eyelids; but it is absurd and inappropriate

in the great majority, at least, of cases of lupus.

COMPONENTS OF THE BLOOD.—The blood contains twelve at least of the *simple* or *undecompounded* elements of matter, the oxygen, hydrogen, carbon, azote, sulphur, and phosphorus, being component parts of animal and vegetable fibrin, albumen and casein, are furnished for instance by meat, bread, eggs, milk, some vegetable juices, and bones.—Sodium and chlorine is derived from culinary salt,—also from eggs and water, most vegetable substances, as the carealea, potatoes, ginger, asparagus, milk, &c.; calcium from water, salt, and many animal and vegetable substances; potassium from milk, fish, and rice; and magnesium from salt, wheat-flour, barley-meal, &c.; silica and manganese which occur in some of the tissues, are introduced into the system with water, the cærealea, and even cucumbers. The only apparent exception is in the case of fluorine, which, according to Berzelius and other chemists, is a component part of the teeth. As an illustration, says Mr. Ancell, let us suppose a child to be fed for six months upon breast-milk alone; we know that iron is absolutely essential for the formation of blood. If the blood have not due proportion of that mineral, healthy nutrition and aeration cannot proceed; the only known source of iron in this instance is the mother's milk, and and according to Pfaff's clever analysis, it contains only a .007th part of the phospate, which, on a cursory view, would appear to be an inadequate quantity. But allowing 12 ounces of milk upon an average as the daily diet, a little more than 10 grains of phosphate of iron would be received into the alimentary canal with the food in six months. This is equivalent to about 5.8 grains of oxide of iron, which, again, is equivalent to about 4½ lbs. of blood. Suppose the child to increase 4 lbs in weight during the six months, and that a pound of this additional weight consists of a permanent increase of the quantity of blood in the system; for the formation of this one pound of blood not more than 1.2 grains of the oxide of iron is required; the remaining 4.6 grains contained in the milk may be deposited in the structures, or eliminated in the secretions or excretions. Iron being one of the most permanent and settled constituents of the blood, employed only in the most minute quantities in the nutrition of any of the tissues, and it being doubtful, whether it leaves the body at all after it forms a part of the blood; it appears to be clearly demonstrated that the quantity above indicated as a constituent of human milk is abundantly sufficient to answer all the purposes of the economy at this period of life.—But let us suppose that from any cause whatever the milk of a particular individual contained a much smaller proportion of iron than here represented—nay 1-10th part of this proportion. In such a case the child would receive from its mother barely enough iron in six months to form 7½ ounces of perfect blood, allowing nothing for waste, or for any portion of the metal which might be employed in the building up of the tissues; it is impossible to conceive that so small a proportion of iron would be consistent with health and progressive growth. Can it be said that the mother's milk is never deficient in its proportion of iron; of potassium; of phosphorus or other elements? Have diseases been referred to their proper causes, and have the most probable causes been yet investigated?

PUS AND MUCUS.—The mode of distinguishing pus from mucus, says Dr. J. Griffiths, has occupied the attention of so many authors, and so many pages have been devoted to its consideration, that any further observations at first sight appear unnecessary. In diseases of the chest, now that the physical examination of that cavity by auscultation and percussion renders us so certain of the disease within, assistance is rarely sought for from either the presence or absence of mucus or pus in the expectorated matter. My object here is to notice one or two of the proposed methods of distinguishing one from the other, and to attempt to show the true relation of pus to mucus. Pus when pure is composed of two kinds of globules floating or suspended in a liquid containing free albumen. The first of these globules are granular on the surface, and much larger than the second, and when acted upon by acetic acid the external part is dissolved, leaving nuclei, varying in number, undissolved; the smaller globules are smooth and transparent, and unaltered by acetic acid. Mucus is composed, as described by Mandl, of globules undistinguishable from pus, irregularly diffused through a viscid tenacious mass which appears itself composed of numerous very minute granules aggregated into amorphous masses, mixed with some very transparent small globules. The larger globules of mucus se m t me undoubtedly to vary in size according to the density of the medium in which they are contained: thus in the ordinary fluid mucus of the nose they are smaller and appear more granulated, whilst in the urine they are generally larger and less granulated, and of a paler colour, seeming as if distended with fluid. Mixed with the various globules in mucus we have abundance of epithelial scales and cells. The viscidity and tenacity of mucus, varying in intensity from the saline watery mucus secreted in acute bronchitis to the almost solid masses sometimes secreted in the latter stages of phthisis and calculous disease of the bladder, is very characteristic, and is worthy (in a diagnostic point of view) of much more attention than it ordinarily receives. It is never found in pus. The fluid part of mucus does not contain free albumen, but it exists in some unknown combination; its presence has been proved by electricity. That variety of morbid secretion termed muco-pus is composed of a large number of *pus globules* suspended in a mucous fluid; there is no true pus secreted in these cases, *i. e.* globules and an albuminous vehicle, but the genuine pus globules in the true mucus. The iron, whose presence in pus has been considered as characteristic, exists in the fluid of pus, not in the globules; therefore, it is not present in muco pus. I have often been surprised, in examining the expetorated "purulent" matter in the last stage of phthisis, where there is an enormous progressing ulcerating surface, and when we should expect a large quantity of true pus to be secreted, at not finding more than a trace of free albumen; although the pus globules were abundant. I believe that Gueterbock is perfectly correct in stating that free albumen is not secreted by mucous surfaces except they be ulcerated; therefore, that pus is not secreted unless under the same circumstances. Pus, when contained in urine, falls to the bottom, and forms a bran-like-layer, which by stirring is readilydiffused throughout the liquid, again subsiding by repose: the urine under these circumstances becomes albuminous.—Wherefore, when this sediment is examined by the microscope, the globules are found in great abundance. Mucus by repose falls also to the bottom of the vessel, but by stirring cannot be diffused through the urine like pus, but retains its peculiar viscid gelatinous appearance. When this sediment is examined by the microscope, the globules are few, and separated by the tenacious fluid. The test proposed by Dr. Young to distinguish pus from mucus shews the fallacy of detecting any one constituent of pus. As is well known, he proposed producing the coloured rings, by placing the suspected matter between two glass plates, and holding it near the eye, and between it and a candle. These rings are, however, readily seen in muco pus when the globules only are present. The recognition of pus by the detection of its fatty matter, as proposed by French authors, would also be equally fallacious.

EFFECTS OF REMEDIES ON THE GENITAL ORGANS.—Cases have been recently published, tending to show that the local use of tartar-emetic or croton oil as counter-irritants *may* produce a curious effect on the genital organs. Dr. Boas has observed an analogous effect produce by assafœtida plaster, which he is much in the habit of employing. In men, tumefaction of the scrotum often occurred; in women, tumefaction and even inflammation of the external labia. In one case, that of a woman fifty years of age, where the plaster had been applied on the abdomen, very troublesome inflammation of the external organs of generation, requiring an antiphlogistic treatment, supervened, and the mammæ became greatly enlarged, and furnished a milky secretion in considerable quantity.

NOVEL CURE OF HYDROCELE WITHOUT OPERATION.

By J. N. ASHWOOD, Surgeon, North Molton.

I WAS attending Mr. E. B., æt. 48, for a febrile attack from getting wet and remaining some time in his wet clothes. He was nearly recovered, but yet in bed, when he mentioned to me a hydrocele which commenced nearly two years before, in consequence, as he said, of a slight blow on the left testis, received in descending from the top of a stage coach, and which, till then, he had concealed from motives of false delicacy. He then only mentioned it as it had, from its size and weight, become troublesome; he complained of some pain in the spermatic cord, and a little soreness and redness of the integuments of the scrotum. I examined it carefully, and found it to be a true hydrocele about eight inches in circumference, and without any apparent disease of the testes. I ordered an evaporating lotion, containing a fourth part of sp. vin rect.; this relieved the pain and soreness in two or three days. One morning, on visiting him, he complained of much painful smarting and soreness of the scrotum; on examination I found the whole surface of its integuments much inflamed and covered with small blisters, as though a blister had been applied and taken off before it had produced its full effects; but, to my surprise and the delight of the patient, the hydrocele was manifestly, and upon its being measured, considerably lessened. I then examined the lotion, which I found, through an error of my assistant, to be entirely rectified spirit. The lotion was at first applied when in bed by means of a single fold of linen, but he had the day before got up and dressed, and used it, being dressed, with several folds of linen,—so that evaporation could not take place, and inflammation was the consequence. I continued the application in its accidental form for a day or two, when he could bear its application no longer; the scrotum was then covered with strips of linen spread with cerat. cetac. until it was healed. The whole of the fluid became absorbed in eight or ten days. The disease has never returned. I had fully determined to operate.

Not long after this I was consulted by a gentlemen about the same age as the former, for the same disease, to whom I proposed the operation; he, however, resolutely refused to submit to any operation. I then mentioned and explained the above case to him, but without holding out to him any confident hope of cure from the treatment; he consented to its employment. It was completely successful, but not in so short a time as the former, as the external inflammation was not so violent.

ROYAL COLLEGE OF SURGEONS IN LONDON.

List of gentlemen admitted members on Friday, December 9th, 1842:—

J. Robinson, B. A. Smith, P. P. Travers, R. Haynes, H. Adkins, T. G. Beall, G Pycroft, T. Jones, E. Empson, T. G. Gurdon, H. J. Sanderson.

ADVERTISEMENTS.

Now ready, 8vo., price 1s.,

MESMERISM, CEREBRAL PHYSIOLOGY, and MATERIALISM, with the Result of the Application of Animal Magnetism to the Cerebral Organs. By W. C. ENGLEDUE, M.D., with a Letter from Dr Elliotson on MESMERIC PHRENOLOGY and MATERIALISM.

London: H. BAILLIERE, 219, Regent-street.

Just published, royal 8vo, bound in cloth, price 9s.

TREATISE on the PRACTICE and PRINCIPLES of HOMŒOPATHY. By Dr. FRANCIS BLACK, M.D. Physician to the Homœopathic Dispensary at Edinburgh.

Homœopathy Explained, and Objections Answered. In 8vo., sewed, price 1s. fourth thousand.

Manual of Veterinary Homœopathy, comprehending the Treatment of the Diseases of Domestic Animals. Translated from the German of M. W. Second edition 18mo., price 4s. bound in cloth.

JAMES LEATH (Successor to Thos. Hurst), 5, St. Paul's Churchyard.

VAN BUTCHELL on FISTULA, &c.—The Sixth Edition.—Just published, in 8vo., cloth boards, price 7s. 6d. (enlarged),

FACTS and OBSERVATIONS relative to a Successful Mode of TREATING PILES, Fistula, Hæmorrhoidal Excrescences, Tumours, and Strictures, WITHOUT CUTTING or CONFINEMENT: illustrated with numerous Cases. Being a familiar Exposition of the Practice of S. J. VAN BUTCHELL, Surgeon-Accoucheur.

"This volume presents to us a number of illustrations of his singular success under circumstances that would have induced despair in any professor of less mastery, or less accustomed to accomplish cures where cures seem impossible. The statements here made are most convincing, and place beyond doubt the superiority of the treatment to which he refers."—Court Journal.

Published by H. RENSHAW, Medical Bookseller, Strand; sold also by the Author, at his residence, 27, Baker-street, Portman-square.

Just published, price 5s. 8vo. cloth, lettered,

A PRACTICAL TREATISE ON CONSUMPTION: its Pathology, Diagnosis, and Treatment; with remarks on Climate, the Use of the Stethoscope, and a Table of the Physical Signs. By FRANCIS COOK, M.D., Physician to the South General Dispensary.

London: JOHN CHURCHILL, Princes-street, Soho.

MESSRS. WHITTAKER & Co., AVE MARIA LANE, LONDON, Have just published, price 30s.,

INFUSORIA. The History of Infusoria, living and fossil, with descriptions of all the known species, arranged after Dr. Ehrenberg, and 500 coloured illustrations. By ANDREW PRITCHARD, M.R.I.

MICROSCOPIC ILLUSTRATIONS. A new Edition, enlarged, price 1s. 6d. with descriptions of the Achromatic, Polarizing, and other Microscopes, and ample instructions for use.
This work is the only practical treatise on the use of Modern Microscopes extant, price 2s. 6d.

ENGLISH PATENTS, being a Register of all those granted in the *Arts, Manufactures*, CHEMISTRY, *Agriculture*, &c., in 1841, with copious Index, and an account of the new Act to secure designs on articles of manufacture.—Also, Second Edition, price 1s.,

A LIST OF 2,000 MICROSCOPIC OBJECTS, with Remarks on the circulation in Animals and Plants seen under the Microscope.

H. SILVERLOCK, MEDICAL PRINTING OFFICE AND LABEL WAREHOUSE, 3, WARDROBE-TERRACE, DOCTORS' COMMONS, London. Where may be had the greatest variety of every description of Labels both Plain and ornamental, for,

Surgeons, Apothecaries, Chemists and Druggists.

. Engraving and Printing tastefully executed.

GEORGE HARRIS, WRITER & LABELLER to the Medical Profession, 15, Little Queen Street, Holborn.—G. H. most respectfully returns his thanks to the Medical Profession, and Chemists and Druggists generally, for the very liberal support he has received as a Labeller and Writer for 20 years, and begs leave to observe, that he now undertakes to fit up Shops and Surgeries in any style of elegance or neatness, and to any price, and trusts, from the great experience he has had with the late Mrs. Willats, Mr. Bruce, and for the last 10 years with the highly respectable firm of Ansell and Hawke, 8, Great Queen-street, Lincoln's-inn-fields, that he will be enabled to give satisfaction.

Stoppered rounds, 1s. per lb., mahogany fronted drawers, 1s. 11d each, labelling in the very best style, 3s. 6d. per dozen. Every article warranted.

GILLOTT'S PENS.

THE QUEEN has been graciously pleased to command that JOSEPH GILLOTT, of Birmingham, be appointed STEEL PEN MANUFACTURER IN ORDINARY TO HER MAJESTY, dated April 13th, 1840.

JOSEPH GILLOTT'S very superior PATENT and other METALLIC PENS may be had of all Stationers, Booksellers, and other Dealers in Pens throughout the United Kingdom.

It is gratifying to the Patentee to acknowledge his obligations to the Public for the best proof they can give him of their approbation, in the continually increasing demand for his Pens.

The number of Pens manufactured at the Works of JOSEPH GILLOTT from Oct. 1838 to Oct. 1839, was 44,654,702, or 3,721,225 dozens, or 310,102 gross, and from Dec. 1840 to Dec. 1841, was 62,126,928, or 5,177,244 dozens, or 431,437 gross.

CAUTION.—All the Genuine Pens are marked in full "JOSEPH GILLOTT," and venders are desired to note that Cards of Pens are made up in packets of 1 dozen each, and have a label outside, with a fac-simile of his signature.

*** At the request of persons extensively engaged in tuition, J. G. has introduced his WARRANTED SCHOOL PENS, which are specially adapted to their use, being of different degrees of flexibility, and with fine, medium, and broad points.

Wholesale and for Exportation at the Manufactory, VICTORIA WORKS, GRAHAM STREET, BIRMINGHAM, and at 37, GRACECHURCH STREET, LONDON, under the management of Mr. Fox, from the Manufactory at Birmingham, or from any of the Wholesale Stationers in London, &c.

THE CHINESE BAND MARCH, as performed on the glorious ratification of peace with Great Britain concluded by Sir Henry Pottinger, arranged for the Piano-forte by H. R. RICHARDS, with a splendid lithographic frontispiece by Brandard, containing a distant view of Nankin, price 2s. 6d.—A PIECE of CHINA, comic song, composed by Loo-Cho Bang-Fang Sin-Song, with a most "splendacious" lithographic illustration of the Emperor of China and his Court, price 1s. 6d.—London: Published by Leoni Lee, 48, Albemarle-street, where may be had Hart's celebrated Chinese Quadrilles, price 4s.

RICHARDS'S VICTORIA SILVER PLATE, FOR SPOONS, FORKS, &c., is proved to be the BEST and therefore the CHEAPEST SUBSTITUTE FOR STERLING SILVER ever produced. It is equal thereto in everything but price. It is a compact solid metal, wrought with the hammer, not plated, and can never wear through the edges, as plated articles do of the very best manufacture. The saving of money is very considerable in the purchase of this excellent article, it being in some cases nearly 80 per cent. less than the cost of Silver. Well deserving the attention of Families, Hotel Keepers, Military or Naval officers, and Travellers of every description.

To be purchased only at RICHARDS'S, LOWTHER HOUSE, 438, WEST STRAND, where are to be obtained also the celebrated Chinese Razors.—N. B. Jewellery of every description.

LABELS FOR FITTING UP SURGERIES, CHEMISTS' SHOPS, &C. AT ABOUT $1\frac{1}{2}$D. PER DOZ.

Just Published, Price 10s. 6d., a new and enlarged Edition,

R. B. EDE'S, NEW, CHEAP AND COMPLETE SERIES of 1,178 LABELS, adapted to the Pharmacopœias of London, Edinburgh, and Dublin, including the New Remedies, and Duplicates and Blanks.—Also, a very SUPERIOR HARD VARNISH, especially prepared for the Series, in Bottles, at 1s. 9d. each.

Dorking: R. B. EDE;—London: Simpkin, Marshall, and Co.; Tegg, Cheapside; and R. E. Dear, 89, Bishopsgate Within.

BRITISH COLONIES and AMERICA. DIPLOMA in MEDICINE. Gentlemen who have completed a Cursus of Medical Studies, and intend to practice in America or in any of the British Colonies, may, through the assistance of the Advertiser, obtain a Diploma in Medicine from a University in high repute.

Address (post paid) to M. D., 15, Tottenham-court New-road.

ORIGINAL MEDICAL GLASS AND FIXTURE WAREHOUSE.

ANSELL AND HAWKE, of No. 8, Great Queen Street, Lincoln's Inn Fields, begs to inform Gentlemen commencing or altering in the above Profession, that they have a large assortment of Drawers, Bottles, Jars, and every requisite for completing Shops or Surgeries, on the most moderate terms. Most satisfactory references can be given as to style and quality. Plans and Estimates furnished, free of expense.

Valuation of Stock and Fixtures.

PORCELAIN LETTERS.—HUGHES and CLARK, Sole Agents for Yates's Patent Porcelain Protecting Letters and Figures, for Shop Fronts, Hotels, Public Buildings, &c. &c., 158, Strand, (adjoining King's College.) These Letters are recommended with perfect confidence as the most durable, beautiful, and economical ever offered to the public. N.B.—Unglazed Letters for Painting or Gilding.

GREAT COATS, Chesterfield and Brighton Wrappers, Travelling Cloaks, &c.—Families and Gentlemen are solicited to inspect a choice collection of the above GARMENTS in various forms and most approved shapes, made in the first style, from every description of patent waterproof cloths, beavers, &c.—M. J. ALBERT'S, tailor, &c., 57, King William-street, City. For prompt payment a saving of at least of 25 per cent. may be effected upon garments of the best description.

SAVE YOUR INCOME-TAX at DOUDNEY and SON'S, 49, Lombard street.—The new and fashionable TAGLIONIS, 18s., Doudney's celebrated army cloth cloak, nine and a half yards, 50s., opera cloaks, 21s., boys' cloaks of every description, from 8s. 6d., superfine dress coats, 35s. and 47s. 6d., frock coats, silk facings, 42s. and 50s., tweeds, buckskins, and tartans for winter trousers, 13s. 6d., 17s. 6d., and 21s., new patterns for winter vests, 7s., and 10s. 6d., suit of liveries, 63s., ladies' riding habits, 63s.—Doudney and Son's, 49, Lombard-street: established 1784.

MOTHES' CAPSULES OF COPAIBA.

"We, the undersigned, hereby appoint Mr. THOMAS BUTLER, 4 Cheapside, London, our sole Agent (in the place of Mr Warrick) for the United Kingdom of Great Britain and Ireland, for the sale of 'MOTHES' GELATINOUS CAPSULES OF BALSAM OF COPAIBA,' of which we are sole Proprietors and Inventors."

MOTHES, LAMOROUX & Co.

Paris, Dec. 17, 1841.

T. B. begs to acquaint Chemists, Druggists, and Apothecaries, that, with a view to prevent the substitution of imitations of the genuine Capsules of Copaiba, he will supply the latter at a considerable reduction from the price which has hitherto been charged for them in this country.

SOLUT. MAGNES. BICARB.—Dr. WILKINSON, of Bath, whose well known familiarity with Practical Chemistry entitles his opinion to respect, says,

"A bottle of the Fluid Magnesia of Sir James Murray's sent to me for Analysis, by a Chemist in this Town, gave me Seven Grains of Magnesia and *Three of Sulphate of Soda* to the ounce, whilst yours yielded Seventeen Grains of PURE MAGNESIA to the ounce. I conscientiously bear testimony to the correctness of the above result.

(Signed) "C. H. WILKINSON, M.D."

"Dated October 23d, 1840."

To Mr C. DINNEFORD, Bond-street, London.

The above conclusive testimony is further corroborated by PROFESSOR BRANDE, of the Royal Institution.

DR. PARIS, author of the Pharmacologia, and Mr. Morgan, of Dublin, who also examined and reported on Sir James Murray's compound.

It has also received the sanction of SIR HENRY HALFORD, Bart., President of the Royal College of Physicians, and the most distinguished Members of every branch of the Medical Profession.

Sold in Jars (for Dispensing only) containing 5lbs., at 5s. 6d. each by the usual respectable Wholesale Houses, or direct from the Proprietor.

MEDICAL.—WANTED, by a Gentleman, aged Twenty-five, a Situation as Visiting and Dispensing Assistant. The Advertiser has had much experience in Midwifery—has been accustomed to Country practice—and can be well recommended by the gentleman whom he has just left. Address (pre-paid), W. M., No. 11, Marylebone-street, Golden-square.

WARM AND MEDICATED BATHS, 5, New Broad-street, City.

THIS Establishment is the Largest in the Kingdom, and is unequalled for comfort, economy, and efficiency of administration. The following Baths are always ready:—Shampooing, Sulphur, Hot Air, Harrowgate, Medicated Vapour, Iodine, Mercurial, and every other description, besides a range of twelve rooms fitted up for the luxury or healthfulness of Warm Bathing. The proprietor is a qualified Surgeon, and daily in attendance from 11 till 2.

LAMPS CHEAPER THAN EVER!—CENTRAL LAMP AND OXYDATOR DEPOT, 14, Finch-lane, Cornhill.

SMITH and Co. have reduced the price of Table Lamps and of all other descriptions, including Reading and Office Lamps, 25 per cent., or one-fourth. No deceptive prices are here put forth, but the public will find every variety of design, from the most simple to the most elegant, at unparalleled low prices. FIREPROOF CHIMNEYS, 6d. each; Purified Oil, 4s. per gallon.

NEW COTTON for ARGAND LAMPS.—The importance of a good Lamp Cotton in the production of light has induced SMITH & Co. to bestow particular attention upon its manufacture. The result has been the production of an article which, from its length of fibre and purity of material, unites extraordinary capillary action with the utmost power of sustaining combustion. For common oils these cottons are indispensable, and for sperm highly requisite,—price no higher than ordinary cottons. 14, Finch-lane.—Merchants and the Trade supplied.

NO LAMP GLASS CAN BE BROKEN where the Patent Oxydator is used; it thus saves more than the cost in three months, and will last a lifetime. It is applicable to the burner of any Lamp without alteration, and increases in an extraordinary degree the luminiferous power of every kind of Oil. Central Depot, 14, Finch-lane.—SMITH and Co. supply the Trade upon the best terms.

EXTENSION OF THE PRINCIPLE OF ART-UNIONS.

THE ROYAL POLYTECHNIC UNION of LONDON.

This Union is founded with the concurrence of the most eminent men in Science and Art, strictly on the principle of giving equal encouragement to both, by promoting the sale of the best productions.

The DIRECTORS of the ROYAL POLYTECHNIC INSTITUTION, with other Gentlemen, form the Committee of Management.

In furtherance of one of the main objects of this Union, viz. that of presenting to every subscriber a valuable work of art, independent of the prizes, which will range from £10 to to £200, and upwards, according to the extent of the list of subscribers, the Committee have been fortunate enough to engage the Members of the Etching Club (some of whom are of the Royal Academy) to produce a work on the same plan (but on a larger scale) as their esteemed edition of the "Deserted Village." It will consist of thirteen finished etchings on ten steel plates, printed on India paper, in an ornamented cover, illustrating a Selection from the Songs of Shakspeare, a copy of which thirteen etchings (TO BE READY IN JANUARY NEXT), will, in order of priority, be presented to each subscriber of 20s., a sum little more than half the price in the usual mode of publication.

In this UNION the whole of the subscribed fund (except the expenses of advertisement and correspondence) will be placed by the Committee in the hands of the Artist and Man of Science, in return for their selected works, the services of the Committee being given gratuitously, thus evincing their determination to avoid the charge of seeking their own pecuniary interest, and preventing the possibility of favoritism by the arrangement that every holder of a prize should be left to make his own selection.

The prizes will be drawn on the 25th of April next, in the presence of a general meeting of subscribers.

Influential residents in the provincial towns, who are disposed to become Honorary Agents, will have the kindness to communicate with the Secretary of the Royal Polytechnic Institution, of whom the Prospectus may be had, and who receives Subscriptions.

309, Regent-street, Dec. 9, 1842.

BENTLEY'S BROWN WINDSOR SOAP is the most emollient and purest soap in use; its healing effects in cases of chapped hands, roughness of skin, or other unpleasant sensations caused by sudden atmospheric changes, are duly appreciated, its constant use will not only protect the hands, face, and arms against bleak winds, and damp air, but it will produce a whiteness and softness of Skin indescribable. In 1s., 1s. 3d., and 2s. 6d. packets. To be had at the Proprietor's Depot for the inimitable Extract of Honey for the growth and restoration of the human hair, No. 220, High Holborn, and of most Hair Dressers and Chemists.

TO MEDICAL PRACTITIONERS.—To meet the convenience of those Medical Practitioners, who (owing to their connection with the Poor-law Unions, or other reasons) are desirous of expeditiously refreshing their Anatomical knowledge, with the view of obtaining the Diploma of the Royal College of Surgeons, also for the accommodation of Senior Pupils, Mr. DERMOTT receives Gentlemen into his house by the month; an arrangement vastly advantageous to those who cannot absent themselves long from their practice. And in reference to the many inquiries of candidates with respect to the extent of indulgence granted on the part of the College, Mr. D. inserts their own official announcement:—

The Court of Examiners have resolved:

"That gentlemen who were practising surgery prior to 1815, be admitted to examination on producing proofs of such anatomical and surgical education as may be deemed sufficient by the Court of Examiners.

"That other candidates be admitted to examinations upon the production of the several certificates requested by the regulations in force, when they have given their professional education by apprenticeship or by attendance on lectures or hospital practice."

Apply to Mr. M. DERMOTT, Charlotte-street School of Medicine, 15, Charlotte-street, Bloomsbury.

. Private Courses of Operative Surgery.

COALS.—SAMSON and Co., Essex Wharf, Strand, and JARROW, South Shields, Coal merchants, Importers, &c., assure their Friends that they have unusual facilities for supplying them with COALS, as they are now freighting direct from the Collieries, and would advise early orders previous to the approaching rise in prices. Very best screened, 25s. 6d.; second, 24s.; Anthracite, for Arnott's Stoves, 29s., within four miles; cyclopic Founders' and Gas Coke, equally cheap.

London: Printed and Published by JAMES ANGERSTEIN CARFRAE, 49, Essex Street Strand, in the Parish of St. Clements Danes, Westminster, in the County of Middlesex.—December 17th, 1842.

// THE MEDICAL TIMES:

A Journal of English and Foreign Medicine and Medical Affairs.

No. 170. Vol. VII. LONDON, SATURDAY, DECEMBER 24, 1842. PRICE FOURPENCE. Stamped Edition, 5d.

For the convenience of Subscribers in remote places, the Weekly Numbers are re-issued in Monthly Parts, stitched in a Wrapper, and forwarded with the Magazines.—Orders for the Stamped Edition [10s. 10d. per Half-year, Post-free in advance,] are received by any Bookseller or Newsman, or may be directed to J. A. Carfrae, Esq., at the Medical Times Office, (late Lancet Office), London.

SUMMARY.

ST. THOMAS'S HOSPITAL.

IMPORTANT CASE OF MOLLITIES OSSIUM.

On Friday evening, Dec 16th, a conversazione was held at St. Thomas's Hospital, when Mr. Samuel Solly communicated the details of a remarkable case of *mollities ossium*, which he illustrated by some drawings and microscopic preparations. Dr. Hodgkin also communicated some original observations regarding the extent and relative position of the thoracic and abdominal viscera in health and disease; the details of which had been communicated to him by Mr. Francis Sibson.

The assembly took place in the large hall of the hospital, which was brilliantly lighted up for the occasion, and there were present not less, we should think, than five hundred persons.

Mr. Samuel Solly, in opening the proceedings, said: Gentlemen, in appearing before you this evening I confess I feel some difficulty in having to address two classes of auditors; for, in addition to the presence of many of the most eminent members of the medical profession, we are favoured with the company of many of those whom it is an honour to see among us, and whom I am proud to see gracing assemblies of this kind with their presence, because it shows that they take an interest in the scientific cultivation of medicine and surgery; not merely, of course, in this school, but all over the world. We know that learned societies flourish not merely by the influence and talent of its superintending members, but by the combination of science with wealth; and we hope, therefore, that the combination of wealthy members in institutions of this kind for the propagation of medical science throughout the globe,—for we know that institutions of this kind are mostly supported by the wealthy part of the community,—I say, I hope therefore, that those who are not practicing the profession will come among us and take an interest in our pursuits and our objects, and will feel the delight that we feel in doing all that may be necessary to communicate all the good that is within our means of bestowment. I say, it is in consequence of my having to address two classes of auditors that I feel some difficulty as to the manner in which I shall address you. If I do not explain myself in language more becoming the theatre of a medical school, and, instead, make use of what may appear trite terms, you must excuse me, inasmuch as I am not addressing simply a medical audience.

The skeleton, it must be known to all intelligent and thinking minds, affords one of the best proofs of a designing and benevolent Providence, and the *bones* of which it is composed are so hard and so firm, that the medical student when he commences his profession hardly looks on it as a part of the living being, and those who have not studied physiology, and know nothing of the science, cannot comprehend that the bones are endowed with anything like a living principle; but those who have studied physiology and the laws of the animal economy, know that they are as much under the influence of vitality as the soft skin that protects them by its sensibility, and which moves so beautifully to every motion of the body. The vital properties of the bones exhibit to the surgeon many wonderful characteristics; he sees that they are under the influences of disease, and also that they are as much endowed with sensibility as the nerves, and the muscles and the other tissues of the body. Many diseases affect them. Scrofula holds not its power from them; the poison which invades the muscular, and especially the pulmonary tissues, also extends itself to the bones. When the bone dies, and is no longer a means of support, nature builds a beautiful protection out of the materials left. Now the sympathetic cyst—which is itself no more than as a small globular particle—possesses the properties of an animal, is capable of reproducing its species: this deposits its seeds in the bones, and thus breaks up the osseous system.

Of all diseases that affect the osseous system, none is more extraordinary, and none more interesting, from its variety, than the *mollities ossium*. The term implies a mere softening of the bone from various causes. It is produced by carcinomatous tubercles in the deposit, allowing it to break easily. In childhood before the calcareous matter has been deposited, they are soft and pliable,—so that, when the deposit takes place, you have that dreadful deformity of the person known under the title of *rickets;* this arises rather from the want of the deposit of calcareous matter than any positive disease. It is true that some physiologists and excellent surgeons have considered that rickets is a disease; Garand, a French physician, brought forward nine facts to establish that it is a disease. Rickets is not a disease which in itself causes the destruction of life; but it is a disease which causes rickets,—namely, the disturbance of the alimentary canal, one of the great causes of the want of a proper assimilation of the food with the blood. It will cause the death of the child; but, supposing the general system to be repaired by the assistance of a medical man, the child may grow up to be an adult, and the deformity will remain. There is a case in a French work in which every portion of the skeleton, the upper and lower extremities, the vertebral column, and the skull, were diseased in like manner; but the disease may be repaired, though the recovery from it be accompanied with deformity. As far as we know at present of the disease, regarding *mollities ossium*, we know that it is a disease *sui generis*—not dependant on any disturbance of the viscera generally; but it is a disease of the cause of which we are ignorant at present, and it is much better to confess our ignorance on subjects of this kind, because we are stimulated to go on in our endeavours to find out the real cause.

The case which has induced me to come before you to night is a case of great interest, and one for the details of which I am indebted to my kind friend Dr. Conolly, and Dr. Davey, of Hanwell Lunatic Asylum, Mr. Dutton, of York-street, Manchester-square, Mr. Temple, and others. I only saw the patient after death. I was present at the *post mortem* examination, at which I assisted, and I made some sections of the bone, made some drawings, and I have followed out the case since and got the particulars. The poor creature, as she laid on a table after death, was so distorted as hardly to present the appearance of a human being.

[We give the report of the case kindly sent to us by Dr. J. G. Davey, of Hanwell Asylum, as being ampler and more precise than that suited to the general audience addressed by Mr. Solly.—Ed.]

C. S. a female, æt. 33, was admitted into this institution in April last. She was much emaciated and enfeebled, and unable, either to walk, or even support herself erect. When not in the recumbent position, she sat on her haunches, supporting herself by her superior extremities, of which she retained a very efficient use. The general deformity of the *skeleton*, induced me to regard the case as one of protracted *rickets*. The bodily health appeared good, the several functions being duly performed; there were no hectic symptoms, or cough, or tumidity of the abdomen, which constitute the ordinary accompaniments of disease of this kind. The history obtained by me from her mother, a very intelligent woman, some months after her admission, is to the effect that in 1837, whilst walking along King William-street, City, she fell, and received a heavy blow on the right knee. The accident confined her to her bed for a period of four months. Before the occurrence of this circumstance she had enjoyed excellent health, but subsequently to it she became very delicate. Her conduct too was characterized by suspicion, and so restless and irritable was her general demeanour, that her friends and relations feared the approach of insanity. All this time, however, she continued to conduct her school, with her habitual precision and care. Her suspicion and timidity at length so much increased that she could hardly be induced to move from room to room. On one occasion, when under the influence of these feelings, she secreted herself in some damp place or other, and thus was attacked (so her mother has assured me) with a severe rheumatic fever, which lasted for six weeks. During the progress of this disease, she made very especial complaint of strange sensations, and occasionally severe pains over the whole head, but more particularly the back part. The cerebral functions too were much disturbed throughout; so soon as symptoms of approaching recovery were manifested, violent *mania* set in, during which she succeeded in inflicting a wound in her throat. After a time the symptoms of insanity moderated, and for the space of fourteen months succeeding the attack, she remained very improperly at home with her family; sometimes better, at other times worse. She was now removed to St. Luke's Hospital, and in a short time was very much better. Her health was *generally* restored, that of the brain as well as the other organs. She became robust. Unfortunately, however, this amendment proved but a too flattering hope of a permanent cure. An attack of epilepsy or hysteria—so it would appear from report—to which I am informed a loss of power of the lower extre-

mities quickly succeeded, proved the precursor of her dissolution. The return of the catamenia which had attended on her improved health, now became suspended. The eyes were observed to grow, as it were from their sockets, and the whole head to increase in size. She was received here from the Islington Infirmary. After admission into the Hanwell Asylum, the deformity of the skeleton abovementioned, (and which was on the whole, of the ordinary character of "*rickets*") went on increasing. The head became larger, the dorsal spine more curved, the sternum more prominent, the lateral parietes of the chest more flattened, the extremities more bent and hoisted, and the articulations more expanded, (particularly those of the phalanges). The appetite continued very good, and the secretions healthy. With the exception of sedative medicines to relieve the severe pains she referred to her bones, she took only a single aperient pill since my knowledge of her. I may add, two grains of morphia (muriate) or a drachm of the sedative liquor of opium produced but slight narcotic effects, such was the severity of her sufferings. The treatment in addition to opiates to relieve pain and procure sleep, consisted in the daily administration of wine, with a generous diet, together with the use of an air bed. Softly padded and small cushions too were recommended by Dr. Conolly with much relief. They were placed in any position likely to relieve particular pressure of parts. She gradually sank, and died on the 28th of October of the present year. I had almost forgotten to state that two or three weeks before her decease, the existence of spontaneous fractures was accidentally discovered.

Autopsy.—The examination detected as many as six spontaneous fractures; viz., two of the left femur, one of the right femur, one of the left clavicle, (nature had made some ineffectual attempts at re-union in this instance) one of the left humerus, and another of the right radius. The viscera of the thorax, abdomen, and pelvis, were *quite healthy*, not a vestige of disease could either be discovered in the brain or membranes. The petrous portion of the temporal bone, on the left side was slightly enlarged. The medullary canals of the long bones one and all, contained a substance, which both in colour and consistence resembled *black currant jelly*. The cancellous substance of all the osseous system with the exception to be specified, was apparently converted into this peculiar morbid product, or, at any rate, the one took the place of the other. The same change was evidently in progress with the outer, or compact structure of the bones. The articulating extremities of the long bones, as the tibia, femur, humerus and those of the fore-arm, were excessively vascular and very much softened; so much so, as to retain very perfectly, even an inconsiderable pressure of the fingers. A section of the upper part of the femur, including the head of the bone, presented an appearance differing only to that which is natural to it, in the greater number and larger size of the cellular spaces, and from which it may be presumed the phosphate of lime &c., had been removed by absorption. A very similar appearance, somewhat modified, was presented by a section of the calvareum which was of immense thickness, measuring in several places seventeen lines in diameter (English). It could be easily cut through with a knife. By exposing the shaft of either the femur or humerus, and embracing it between the finger and thumb, the compact substance easily yielded to the pressure, so very thin was it, and imparted the sensation of breaking a soft shelled walnut.

My friend, Mr. Solly, of St. Thomas's Hospital, who happened to be present, intends, I believe, to furnish the profession with the result of an analysis both *chemical* and *microscopical* of the peculiar substance abovementioned.

Remarks.—Even supposing that pathologists were agreed respecting the precise nature of disease, of the kind I have narrated; nevertheless, I should consider that the unfrequency of such cases as that of C. S., would excuse the publication of the present one. In the note, Mr. Editor, which prefaces the observations I have submitted to you, I have designated the case one of *mollities ossium*, you will, however, perceive that I have affixed a *query* to the term. I should be glad to learn of any one of your numerous and talented correspondents in what consists the difference, not *nominal* but *virtual*, between rachitis, fragilitas ossium, and mollities ossium. Are they not I would enquire, mere *words*, signifying but varieties of the same disease? I may be told, that the first is confined to childhood. That such is the generally received opinion is most true. Yet are we not without authority to show that such an opinion is ill founded.* Mr. Cooper in his surgical dictionary, quotes a case by Morand (Acad. des Sciences, 1753) "in which an *adult* became affected" with this disease. And we learn too from the same author) that the late Mr. Wilson was agreed with Boyer and Richerand in believing rickets and mollities ossium to be "one and the same." The interesting case of "*mollities ossium*" recorded by the late Mr. Gooch, and given in the article of that name in Mr. Cooper's surgical dictionary was preceeded by a remarkable fragility of the bones. A circumstance, which, when taken in connexion with the fact that "in almost all the cases on record, the fragilitas and mollities have been combined," leaves little room to doubt their identity. In the case of C. S., nothing could be more striking than this combination. The shaft of the long bones were in a state of fragility, the articulating extremities of the same bones being softened; I am strongly disposed to think that independently of any *chemical* changes, so to speak, in the osseous system, whereby the relative proportion of earthy and animal matter is lost, giving rise to an excess of one or other of the essential elements of bone and constituting thereby either a pure softening of its texture, in which it becomes completely FLEXIBLE, and loses all its natural firmness, the effect ONLY of a deficiency of lime, and *without other morbid changes*; or an increased hardness, or brittleness, the mere consequence, as above explained, of the loss of balance of the organized and calcareous structures, in which the latter preponderates, as is seen in old persons, and whereby they are rendered more liable to *fracture*,—cases which are *without other organic change* than that now detailed. I say, that independently of such changes, and which, perhaps, we do well to recognize by the general and certainly more expressive terms of mollities and fragilitas ossium; I believe there is a peculiar and specific disease of bone, the real nature of which is at present misunderstood, and which in its accession, progress, and termination, presents certain *physical* characters, from which alone all our ideas of it have been conceived, and hence the employment of the terms in use; and such a disease it will be readily seen, I presume, is realised, in the case which I have reported. To recur, however, to the *question*—if such it be—of rickets, fragilitas, and mollities ossium, I would beg leave to draw the attention of the reader to the appearances observed after death. In Mr. Gooch's case before-mentioned, it was observed, that "all the bones, except the teeth, were softened, so that scarcely any of them could resist the knife; but those of the lower extremities were most dissolved, being changed into a *kind of pulpy mass* [illegible] *red liver, with an* [illegible] so completely, indeed, were they decomposed, that the knife met with less resistance in cutting through them, than in sound muscular flesh, though some bony laminæ were here and there to be met with, but as *thin as an egg shell*. The most compact bones, and those which contained the greatest quantity of marrow were the most dissolved; and it was observable, that the dissolution began internally; for the bony laminæ remained here and there on the outside, and nowhere else." Boyer gives the following description of *ricketty bones*.† They are lighter than natural, and of a *red or brown* colour. They are penetrated by many enlarged blood vessels, being porous, and, as it were, spongy, soft, and compressible. They are moistened by a sanies, which may be pressed out of their texture, as out of a sponge, or rather a macerated hide after it has been tanned." No description more correct could be given of the appearances presented by a section of the skull in C. S.'s case. "*The walls of the medullary cylinder of the great bones of the extremities are very thin, while the bones of the skull are considerably increased in thickness, and become spongy and reticular.* All the affected bones, especially the long ones acquire a remarkable suppleness, *but if they are bent beyond a certain point they break, &c.* Instead of being filled with medulla, the medullary cavity of the long bones contains only *a reddish serum*, totally devoid of the fat, oily nature of the other secretion in the natural state." These words of Boyer apply with great force to C. S. In her case, if the long bones were "bent beyond a certain point" they broke. I tried the experiment. Mr. Stanley has found the interior of ricketty bones occupied with "*a brownish gelatinous substance*." If in ricketts the bones retain their *natural* INFLEXIBILITY, which they do not in mollities ossium, but may be at once bent in any direction, then was the case of C. S. *not* of this kind, but rather one of "*Rachitis*." The pathological changes above quoted from Gooch and Boyer respectively, if contrasted, will go far to shew that these authorities have here described the same disease, with different names *only*. Dr. Cumin says, "As the disease (rickets) proceeds, *the bones are readily fractured* whenever a slight force is applied, and it is remarked that, *softened* as they are, they usually re-unite; at length they become completely suppliant."

It is usual to regard rheumatism as a cause of mollities ossium; undoubted cases of this disease are, however, on record, in which no such cause appears. The severe pains which mark the accession and progress of this very peculiar morbid action in the bones, it is very likely are often erroneously considered as rheumatic,—though, in the instance above recorded, it appears probable that C. S. did suffer a severe attack of rheumatism, inasmuch, as for a long period subsequent to that which is mentioned as such, she was without pain, &c.; and, before this, I could learn of no particulars to enable me to trace the origin of the disease to so early a period.

I shall now, said Mr. Solly, continuing his observations, refer to a few other extraordinary cases. M. Jupé was born in 1817. Her case bore great resemblance in the general details to the case I have related to you; but she lived longer under the influence of the softening of the bones, and, therefore, there was a distortion of the limbs. Her posterior extremities were actually drawn over her head, and her arms were bent and twisted, as you would twist a simple piece of string. The case of a male individual came under the care of Mr. Thompson, of the London Hospital; this individual lived to the age of thirty-three. A case also occurred in 1776, and many other cases are recorded; but the case most detailed is that recorded by Mr. Howship, and another is detailed by Mr. Curling in the medico-chirurgical transactions. In the case related by Mr. Howship the disease lasted six years, during which time the patient had the benefit of the sea air; and Mr. Howship says, "I feel convinced, had the patient remained eighteen months at the sea side, she would have returned home perfectly cured." About twenty

---

* "The softening of the bones, which is met with in persons of adult or advanced age, presents itself in various degrees of severity. Sometimes it is merely a [illegible], which has continued with numerous checks and interruptions, and successive revivals and increase of symptoms [illegible] *advanced life*."—*Cumin*.

The same writer mentions too a case of "*mollities ossium*" in a child four years old.

† The late Dr. Cumin in the the article "*mollities ossium*," (Cyclop. of Practical Med.) describes the appearances on inspection after death, *in this disease*, as precisely similar to those regarded by Boyer, as *characteristic of Rachitis*.

cases are on record, and it is curious that in all these cases the *post mortem* appearances present an extraordinary resemblance one to another; the larger bones contained a thick red liver-coloured matter, except in cases where the individual's life was cut short by a violent attack of bronchitis, then the bones contained matter of a jelatinous character and a pale brown colour. This is very interesting, as the patients' lives were cut short in the early stage of the disease. All these cases were accompanied more or less with rheumatic pains, and in the early stages with more or less of a deposit in the urine of a cretaceous character; as the disease advanced, and the bones became softened, then the urine became clear. With regard to the probable causes of the disease, I confess, at present, we really are as much in the dark about them as we ever were; rheumatism has been referred to as the cause. There are pains which naturally attend such a disorganization as is occasioned by this disease, and these pains have been regarded in the light of an acute rheumatic attack, rather than that rheumatism has preceded the invasion of the disease. For instance, in the case I have just related, the unfortunate individual at the age of eighteen, fell down and fractured her collar-bone, but it was not until after that, that she had an acute attack of rheumatism; therefore, there must have been some other cause of disease existing before, and the rheumatism afterwards. The disease I have been describing spares neither sex nor age. It is not limited to the female, though there are some curious cases of the softening of the pelvis, and in these cases, the softening is limited to the bones of the pelvis, and not extending further; but we find it occuring also in the male subject. It does not occur merely in infancy as rickets,—nor is it limited to children; but it affects adults. The case related by Mr. Curling occurred at the age of seventy one, and there is a preparation of this disease in the Anatomical Museum, taken from a woman at the age of eighty. With regard to the appearance of the viscera generally, they are healthy; sometimes the liver is found enlarged, but the lungs and the alimentary canal are found in a perfect state of health. Some writers have set it down as an established fact that it is the result of gout. There appears some connection between this disease and scurvy, for in many cases the gums have separated from the teeth. I hope any one who has an opportunity of examining cases of this kind will take care to examine, so as to be able to detect any alteration of the causes of scurvy and purpurea. Mr. Curling thinks it is merely a case of atrophy of the bones, and not a peculiar disease, that the matter in the canals of the bones is merely the fatty matter of the bones stained with blood. This disease is not limited to the human being, but it has been found in animals. Mr. Spooner, of the Veterinary College, informed me himself that he had sent to him several hounds from the kennel of Lord Milton; of these, first one dog was attacked, and then the whole progeny; it went through one portion of the kennel to the other. Now in this state of doubt and dilemma I began to think at one time that we had found something like an explanation of the cause; for sections of the bones of this individual were placed under the microscope by an exceedingly intelligent gentleman, who has had great experience in the use of that instrument, and he found, on examining portions of the bones, some particles of matter, which he believed to be worms. These were examined carefully, and they were supposed to be worms. I therefore examined the matter very carefully, and I repeated the examination of those bones with some men who are in the habit of looking through the microscope, and I found that the supposed worms were little filaments separated from the bones, and the conclusion we came to was, that they were not worms, but extraneous matter forced into the sections by the cutting knife, because the cleaner we cut the sections there was less appearance of worms, and at last, by the greatest care, not a portion of the supposed worms could be seen in the section. We made twenty sections, one after the other, most carefully, and not a single worm nor animal could be distinguished. The fact is a curious and interesting one, in connection with the study of the microscope. You should at all times be very careful in all microscopic observations. I have now completed all that I have to communicate on this interesting case. I trust you will excuse me if I have been rather brief, and take the will for the deed.

Dr. Hodgkin then communicated to the meeting a very interesting paper on some peculiarities of the thoracic and abdominal viscera, which we shall give next week.

PRIVATE COURSE OF OPERATIVE SURGERY.

By J. NOTTINGHAM, Esq., Member of the Royal College of Surgeons of London.

LECTURE VI.

We now proceed to treat of the means employed by surgeons for closing divided arteries, and in the next place to speak of the precautions to be observed for preventing hemorrhage from wounds after the latter are closed.

Where small arterial branches alone are cut across as in the wounds of the superficial parts of the body, they may often be left to themselves with impunity, for the divided twigs of artery cease to bleed, as soon as they have become a little retracted, and the immediate effect of the stimulus which a cutting instrument may have produced, has abated in the affected part.

Sometimes, however, a bleeding from small arterial branches of this kind has continued longer than we desire or approve of. If the mouths of such vessels can be seen, they may be seized with a tenaculum or dissecting forceps, and then secured by ligature in the ordinary way; if not, the part whence the arterial blood issues may be seized with forceps broader at the point, and a torsion effected of all that is thus laid hold of; in this way the bleeding may generally be arrested. Sometimes the mere squeezing of the parts with the fingers is sufficient to answer the purpose, or the forceps may be employed in the same way, squeezing the parts, and thus breaking more or less the internal membrane of the arterial branches, without attempting any torsion of them, for the breaking or lacerating of the inner coat of the arteries helps the formation and the after tranquillity of the internal clot, by the settling of which further bleeding is prevented; or it may be requisite to apply the ligature to the artery or arteries, along with neighbouring tissues, when the vessels cannot be detected and isolated.

In the larger operations, such as amputation of the limbs, removal of the breast, &c., various modes of securing the divided arteries have been adopted at different times, and in the recent progress of surgery, these have become more numerous than useful; we shall not however in this elementary course attempt to name, much less to describe many surgical curiosities of this nature; they have been more numerous on the European continent than in these countries; but here, as every where else, the greatest masters of the art have generally contented theselves with the simplest methods of operating; to such of this kind, therefore, as are generally adopted by the most distinguished surgeons of the present day, the remarks we now make will be chiefly confined.

In the old-fashioned or circular amputation, there is, perhaps, less difficulty in effectually securing the arteries than in the flap operation, so often performed of late, for in the former operation, where the arteries are evenly cut across perpendicular to their course, the end once being seized with the forceps or tenaculum, there is no difficulty with regard to the application of the ligature, nor is there, generally speaking, any fear for the complete security of the vessel so tied; not so, however, in the flap operation—here the catlin does not cross the limb, but is slanted through it, if the expression may be allowed, the vessels are divided obliquely, and present frequently long spoon-like mouths on the exposed surface of the flap, the ligature must be applied with care fairly above the highest point of the section, and generally in this way the bleeding for the time is arrested. It may happen, however, that a small arterial branch arises from the trunk a little above the point where the ligature is applied, which in some cases will be divided near to its origin from the main vessel, and this latter being secured below by ligature, admits afterwards of hæmorrhage occurring from the unsecured twig as soon as a little reaction takes place in the system of the patient, so that the possibility of such an accident should put us on our guard, lest by overlooking a divided arterial branch, such as we now allude to, an after bleeding should occur, always troublesome, and a source of the greatest anxiety to the surgeon, at the same time dangerous to the patient, and besides all this, frequently giving to him more pain in opening the stump (already sensitive and sore) than that which the previous operation produced.

In seizing an artery about to be tied, it may be transfixed at its divided extremity with the tenaculum, and then drawn out—or with the forceps, one point being inside its calibre, the vessel may be pulled forth by pinching one side in the forceps, or without being so particular or so artistic as this, we may be contented with the plan which most surgeons adopt, of laying hold of the end of the vessel with the point of the instrument, caring merely to isolate it completely, and at the same time to get good hold, for in this way the application of the ligature is easily made secure, as we place it far enough on the end of the vessel brought forth to prevent it slipping off afterwards, and thus all the purposes of its application are attained.

In most cases the vessel may be separated from the parts to which it more or less adheres so as to enable us to tie it without including an accompanying vein or nervous filament; it may, however, sometimes be better to allow a little cellular tissue or muscular fibre to enter within the loop of the ligature, than to run any risk by an over-nice dissection of injuring the coats of the artery before the thread is applied to it.

Ligatures should be examined as to their strength before their employment by the surgeon. Common hempen thread is no doubt the best material, its thickness must depend on the size of the vessel to be tied, for the femoral artery for example; a good ligature is that kind of shop-thread, now so commonly employed for tying small parcels, &c., and, if waxed, the making and closing of the noose is somewhat facilitated; one end of the ligature may be cut off, the other allowed to hang from the lower end of the wound. Some surgeons prefer cutting off both ends of the ligature close to the knot; others like to employ ligatures made of animal substances, thinking that after they had acted as ligatures (of course not before) they would be absorbed, and that the constitution of the part would have mercy upon them, and not treat them as foreign bodies. I may be allowed an egotistic shortening of these remarks, by saying, that if I were a patient, I would have no such refinements practised on me.

In applying the dressings, as in cases of amputation of the leg for example, it is better to adapt all the straps of plaister employed in uniting the sides of the wound, and then gathering the ends of ligature together, let them be fixed over the plaister by a separate strap of the same material, for thus left, they come at once into the view of the surgeon at the time of the first dressing, and may be treated in such a careful manner, that their at-

tached extremity will not be disturbed, as occasionally happens in cases where at the time of the first dressing they are applied to the skin, and have the plaister stuck over them.

We now come to consider whether any considerable interval of time should elapse between the application of the ligatures and the closure of the wound, or whether immediately after the securing of the blood-vessels, the sides of the wound should be brought together: and here we may call to mind the issue of two cases of operation for cancer of the breast, treated one in one of the ways mentioned, the other in the other. In the first case, I allowed the parts to remain exposed for a time after the ablation of the diseased mass, subsequently, straps of sticking-plaister were applied in the ordinary way; in this case we had no secondary hæmorrhage: in the second case, the edges of the wound were approximated immediately after the removal of the tumour; there were some peculiar reasons for this practice connected with the then state of the patient, hysterical fainting, &c., making it desirable that we should put her quietly to bed as soon as possible; in this instance secondary hæmorrhage followed, and without taking up more time by extending the comparison or the contrast of the cases, we may be allowed to add, that it is at least probable that the secondary hæmorrhage in the last case might not have occurred, had the exposure after the operation been resorted to, and the edges of the wound only brought together, when an hour or two had elapsed after the time of its performance.

The remarks on this subject on the "*Clinique chirurgical*" of Dupuytren deserve to be remembered, for he always allowed one or more hours to pass after the performance of any of the greater and cutting operations before the wound was definitively closed. His practice is spoken of in the following manner:—"The patient is put to bed immediately after the ligature of the blood-vessels, nothing being now applied save a compress, lightly supported by a few turns of a roller; the following reasons are assigned for M. Dupuytren's practice."

It frequently happens, despite all the cares of the operator to tie most precisely every vessel whence a jet of blood or oozing comes forth, of whatever calibre the vessel may be, that shortly after the operation consecutive hæmorrhage occurs, always injurious to the patient, and obliging the practitioner to remove every part of the dressings applied. In no case can we be certain beforehand that such an accident may not occur: and supposing the dressings to be applied, the bleeding might not be discovered until they had become steeped, more or less with blood; in other words, when the hæmorrhage would already have produced very deleterious effects on the system of the patient. Of this occurrence M. Dupuytren gives the following explanation:—In some cases there are arteries which although not tied, do not send forth any blood; their extremities are not observed on the surface of the stump, retracted and hidden in the surrounding structures, they do not allow the escape of any blood. In such cases it is in vain to wait for a few minutes merely, for no hæmorrhage will appear; but allow one or two hours to pass, or in some instances a much less time, and the irritation will attract the circulating fluids to the part, and secondary bleeding will show itself. This absence of the flow of blood at the time of the operation often depends upon the deep moral impression which the idea of it has produced on the patient, or on spasmodic actions, more or less violent, from which he has suffered during its performance. Some patients there are who faint from fear, or at the sight of blood flowing over the cutting instruments; two or three hours afterwards, secondary hæmorrhage not unfrequently occurs in such cases, this being produced by the greater afflux of blood to the part, and by a dilatation of the vessels, which at first did not appear: or such hæmorrhage may, in some instances, be accounted for by some imperfection in the mode of applying the ligature. Since M. Dupuytren has taken the precautions now alluded to, there has not been a single case of secondary hæmorrhage in any patient operated on by him at the *Hotel Dieu*. In the interval between the operation and the dressing, an intelligent assistant watches by the patient, provided with all that is required for the temporary suppression of any hæmorrhage that might occur.

Although the practice of M. Dupuytren be not generally adopted, and many surgeons continue to close and dress the stump in cases of amputation immediately after the blood-vessels are secured to their satisfaction, we cannot quit these considerations without expressing our admiration for the practice here recommended, calculated as it is to ward off a most disagreeable duty, which the surgeon is now and then called upon to perform; for imagine yourself sent for in the middle of the night to a patient who is said to be bleeding, who has, perhaps, had his leg amputated the day before at noon, frightened, and fainting—friends alarmed, and paralysed by their fears; the faces of the bystanders pale, their hands helpless—you find the bandages distended and soaked with blood; you undo the roller, and remove the straps of plaister, finding the stitches on the stretch, or perhaps burst open, and the flaps bulged apart by the huge clot between them, which must now be removed; the patient screaming with pain under this operation of tearing the adhering fibrin from the inner surface of the raw flaps, whose sensibility is already much heightened by the irritation which the first operation has set up: with the light, perhaps, of a few candles which only serve to make darkness visible; after tearing away (for this is the fittest expression) the coagula which clung to the hollow of the stump, you must grope with the tenaculum or forceps for the vessels where the blood is supposed to come: perhaps no such bleeding vessels will be found, for if we may be allowed so to speak, it often appears that they have bled as much as they choose to bleed, and here is an end of the matter as far they are concerned. Groping with the tenaculum or forceps, is an expression which may be here allowed, for in reality, even had we good light we cannot see our way on these occasions, when some vestiges of coagula will more or less mask the face of the stump, and hide the mouths of the vessels, which are seen with comparative facility soon after the knife has passed through them, or before they are concealed by bloody deposit, and all this will now and then happen, if we do not take those precautions which are recommended for the preventing of secondary hæmorrhage; but all I think must be agreed respecting the horrible nature of the accident above described, and of the importance which ought to be attached to those rules of practice which will often enable us to avoid such occurrences, not less distressing to the surgeon than they are dangerous to the patient.

When the patient is removed from the operation table and placed on his bed, there is no reason why the atmospheric air should not reach the surface of the divided parts during an hour or two after the operation, and when subsequently the dressings have been applied, cold water may be employed upon and around them, more especially if we have to deal with very irritable subjects: if much excitement be likely to follow the operation, or the hæmorrhagic tendency, be greater than usual, the employment of opium, digitalis or preparations of lead internally, or the application of local styptics, powders of kino or dried fungi, and other such like matters externally, if noticed in detail would carry these observations far beyond the limits assigned to them, we shall, therefore, leave this department of our subject, and betake ourselves to that which seems most naturally to follow it, and as we have already spoken of incisions, and of the bleeding which follows their formation, we now proceed to treat of

REUNION,

Or the closure of wounds after hæmorrhage, from their surface, has been arrested. In union by the first intention, the sides of the wound which the surgeon has brought together, are united more or less firmly by a process of vital agglutination, within a few hours from the time of its infliction, the separated portions of divided skin in such cases being fitted to one another time is not required for the formation of new cuticle.

In union by the second intention, a wound must fill up by granulation from the bottom and sides during this time the superficial part of the wound is observed to contract; and, lastly, the new integument of the scar going from all parts of the borders of the wounds ultimately unites itself in the middle to finish the process.

After a great number of surgical operations, we endeavour to obtain union by the first intention. After a few, however, union by the second is sought for, the applications of either mode of union will be explained as we proceed.

In cases of wound inflicted by accident, coagula and foreign bodies must be removed and bleeding arrested, the part placed in as easy and relaxed a position as possible, occasionally lacerated portions of integument or deeper structure taken away, and then the sides of the wound approximated, never allowing any uneasiness from tension in this approximation. In many such cases it is useless to hope for union by the first intention, so that if the aspect of the wound be such as to warrant our supposing that this is not possible, the treatment must be directed to the favouring and shortening of the granulating process, applications being made which tend to keep the parts clean, and to regulate their temperature, and these being changed as often as circumstances require. One extremity of the solution of continuity should be placed, if possible, lower than the other, to favour the exit of discharge, and thus prevent an injurious accumulation of it between the sides of the wound.

It is to be hoped that the vigorous and valuable remarks of Mr. Liston on the abominations of the poultice system, and all the filth attending it, will have the effect of bringing its application within a much narrower sphere than it has of late years enjoyed, for surgeons once being convinced that warmith and moisture are all that is useful in poultices of the ordinary kind, will no longer seek on every occasion to bedaub a wounded part with boiled bread or linseed meal, when by lint, steeped in water of a proper temperature, applied to the part, and the covered with a little oiled silk, the state of moisture and warmth can be maintained, and cleanliness duly preserved.

The constitution of the patient, the organization of the part, and the nature of the injury inflicted, must be attended to even in the choice of our local applications; heat or cold, stimulants, sedatives, or anodynes, all within our reach, being taken advantage of as circumstances may require; these considerations, however, can hardly be said to belong to our subject.

In the every day practice of surgery, we see two kinds of suture employed, which might be called the simple, and the compound or complicated—simple, when thread alone is used as the uniting medium—compound when any addition is made to this—as in cases where hare-lip-pins are passed through the lips of the wound, and the thread in figure of 8 turns twisted over them, or where pieces of quill or bougie are laid along the border of each lip of the wound, and double ligatures tied over them, so as to approximate the deeper parts of the solution of continuity by thus drawing the two quills towards one another.

The simple or interrupted suture, answers well in a great number of cases, a single or double thread, according to circumstances, being passed from without inwards with regard to one side of the wound,—from within outwards on the other. In passing the needle, the parts of the wound should first be evenly put together, made to fit well, but not with the employment of any considerable force, if they do not approximate with ease, it is more than probable that union by the first intention will not take place, and that we had better look forward to a granulating process than be disappointed about the others. While the edges of the wound are approximated, and in neat contact, the surgeon may thrust his needle through both lips of the wound at once and with facility: this is better than the plan of introducing the needle with the lips of the wound apart, first taking one portion of the integument, and then the other; for in this way, unless great care be taken, we shall not obtain that even junction with the sutures which is

insured by adopting the former method. In most cases we may pass a suture through the middle of the wound first, afterwards those towards the extremities may be introduced; the principal exceptions to this plan are in those cases where the free border of a part has been wounded, either by accident, or by operation, as in the lip, or eyelid, here the free margin had better be neatly united first by the suture, which is to be passed near to it, the other sutures, if more be required, being introduced afterwards. The degree of hold taken by the sutures must depend upon the size of the lips of the wound, and upon the apparent chance of immediate union by the first intention, for if the wound be large, a little more hold must be taken, and if it would seem that union by the first intention is doubtful, this is also a reason for giving to the threads such hold of the part as will enable them to continue their office a little longer without ulcerating more than might otherwise have been required.

Needles that are straight in three-quarters of their length, and only a little curved towards the point, in most cases answer our purpose very well. In uniting the flaps after amputations, straight needles, ground prismatic, or trocar-shaped towards the point, sometimes called glovers' needles, pierce the integument with facility; and in such cases, where the curve is not wanted, are, perhaps, the best. In passing sutures through the lips of a wound, in any concave region, such as the neighbourhood of the angle of the jaw, the axilla, or perineum, the old-fashioned curved, or almost semicircular surgical needle, may be employed with advantage.

With regard to the complicated sutures, we may remark that the hare-lip pins are more especially useful where there is any considerable drag upon the sides of the wound, either on account of position, and the weight of neighbouring parts, or from the tension, and consequent tendency to separation, which antagonizing muscles produce. This latter remark, having more particular reference to the lips, the hare-lip pins should be long and small, and of some material that may be cut easily at the extremities, after introduction—such as silver, or steel not too much hardened: the pins with moveable points, belong to the ingenious complications of by-gone surgery.

After the operation for hare-lip, the blood which oozes from the part into the thread which is twisted over the pins, glues the thread in a mass over the wound, and forms an additional bond of union for a time—which I have found in many cases adhered very well after the pins were withdrawn, provided the latter be taken out in a careful manner, so as not to disturb the adhesion of the thread to the lip. It is not easy to fix any time for the withdrawing of the hare-lip pins, but our attention should be frequently directed to the state of the part, from the end of the second until the end of the fourth day—provided we have not extracted them before the latter period—by which time the union likely to take place, will generally have been effected. It is always desirable to prevent sutures having any chance to come away by ulceration; and this is more especially the case with regard to hare-lip pins. I have known this accident to occur from over-anxiety on the part of the surgeon to get a complete union before the pins were withdrawn. In this way, transverse scars were added to the perpendicular one, producing a corrugated and disagreeable appearance on the lip. As there is nothing in the quilled suture particularly worthy of notice, saving the couple of compresses which it gives to the wound, we need not dwell either upon its peculiarities or application.

In the dressing of wounds generally, I would recommend not much bandaging, still less plaistering. The isinglass plaister of Mr. Liston (made by Messrs. Fisher and Toller, Conduit-street, and Bell, Oxford-street,) being much less irritating than the ordinary sticking-plaisters, should be generally preferred to them in cases where calico bandage, or other uniting medium, is at the same time employed; this remark having reference to the fact, that, unassisted, it might in some cases, be too weak as a single means of union.

The lower or depending extremity of the wound through which the collected ligatures may hang on cases where arteries have been tied, should not be closely plaistered like the parts above it, but allowed to give exit to any discharge that may flow by the side of the threads it contains. After amputations, I have lately not carried the roller over the end of the stump, leaving the parts in such a state, that the progress they make may be more or less observed through the transparent isinglass plaister. With regard to the mode of tying, or knotting ligatures, either in applying them to arteries, or in closing the interrupted suture, the common double noose, reversing the ends of the ligature in the second half, appears to me to answer every useful purpose, to this, of course, an additional knot would be in no way prejudicial.

PRACTICAL OBSERVATIONS ON THE NATURE, PECULIARITIES, AND TREATMENT, OF SOME OF THE MOST PREVALENT DISEASES, &c. CONNECTED WITH THE POPULATION OF NORTH CHESHIRE, AND SOUTH LANCASHIRE, EMPLOYED IN COTTON FACTORIES.

By Charles Clay, Member of the Royal College of Physicians, London, College of Surgeons, Edinburgh, and Lecturer on Medical Jurisprudence and Medical Police, Manchester.

In recording the following observations on some of the diseases most prevalent to that part of the community employed in cotton factories, particularly in a widely extended manufacturing district, with their peculiarities, and mode of treatment required under such circumstances, I shall be obliged to pursue the enquiry at considerable length, as some parts of the subject will naturally include circumstances connected with the locality, as situation, temperature, occupation, habits of life, food, clothing, &c.

The subject, though an extensive one, will be much more limited than if I had included the peculiarities of disease, &c., connected with other extensive occupations in the same locality, (as I intended originally to do.) In selecting the operatives of the cotton factory department, for the illustration of my present essay, I am guided in a great measure by numbers; as it must be allowed that they form the majority, and that a very considerable one, of the population of the district referred to. By this isolation, however, I do not mean it to be understood that the factory-employed hands are the only ones requiring the special attention of medical writers, but simply that the whole subject may be brought within the reasonable limits of a journal communication, leaving the question still open respecting other occupations which may form the subjects for subsequent enquiry, of equal importance with that of the present essay.

The fact of having passed the whole of my professional life amidst the densely populated manufacturing districts, will, I hope, be a sufficient apology for these observations, it being my conviction that the best evidence is that gleaned from the locality, the result of extensive practice and long observation of facts carefully recorded.

It is not my intention to extend these observations to an unnecessary length, by including diseases attacking only once in life, or those equally prevalent in other occupations, as both may be considered as more applicable to general rather than to particular classes of society; and will much shorten the matter under consideration.

In order to facilitate the method of enquiry, I shall divide the subject into sections. The first, from birth to the completion of the second year, the second, from the second to the fourteenth or fifteenth year, the third, from the fifteenth to the twenty-first, the fourth, the adult period of the female, the fifth, the adult period of the male, and the sixth, the declining period of life in both sexes. I have adopted this division that the diseases of each period of life may be better understood as to treatment. By directing the attention of the profession to a particular locality connected with any extensive occupation, I conceive much valuable information may be elicited, that may be of use to those destined to pursue their professional exertions in the same, or similarly situated localities. I well recollect many instances of professional men coming, hot from their studies, into the manufacturing districts, fully armed with the principles and practice of medicine and surgery, as taught by professors; whose experience has been (though extensive) founded from localities of a very different description, the diseases of which required a difference of treatment from the differences presented in the occupations, habits of life, food, clothing, &c. To such an extent may this error operate, that a line of treatment perfectly justifiable, and successful in one locality, may, when applied to another, be equally absurd and fatal. As an illustration, I might refer to the difference in character of typhus, in a stout, athletic, out-door labourer, in an agricultural district, when compared to the same disease in a weak, lax-fibred, emaciated subject, employed in a cotton mill of high temperature, and subject to constant exposure to the changes from that artificial heat, to a cold moist atmosphere without. How often have I witnessed fatal results in the practice of junior practitioners, from the use of the lancet in the early stages of typhus in the lax-fibred occupants of the manufacturing districts.

It would be impossible to approach this subject without admitting the fact that must be evident to every reflective mind, namely, that a manufacturing community must inevitably be a depreciated one, in respect to the physical powers of the human constitution. "Whoever has formed an idea of the English from Voltaire, would be surprised to find the rosy cheeks and robust athletic forms he talks of, changed into pallid faces, and weak, unsteady frames, that characterize the mechanics and cotton mill hands of manufacturing localities. The spade improves a population, but the loom spoils it. What a difference between a Scotch highlander and a Glasgow weaver! The one still retains the well-knit athletic form of the warriors described by Ossian; legs like the marble column of Lena, a breast high and ample as a cuirass, the colour of vigour in his cheeks, in all his deportment the fire and mettle of health and strength. The other on the contrary, is lean, ill made, old before his time, and feeble in his gait. What a contrast between an English coachman and a Manchester spinner! The former is the very model of Bacchus,—the latter of a prisoner for life."

Of late, attempts have been made to prove that the population of large manufacturing towns was not more unhealthy than others differently situated. In the recent returns under the registration act, the town of Liverpool, where little or no manufacturing is carried on, shews a higher rate of mortality than even Manchester, which is almost wholly a manufacturing population.

If there existed no reason for doubting the correctness *not of the returns themselves*, but their application to this question, it would indeed be a startling position, and of very difficult solution, but I conceive there exists sufficient evidence to prove the application fallacious.

It must not be overlooked that Liverpool has an extensive sea-port trade, causing a great influx of foreigners from various climates, subjecting them to the disadvantages of our variable climate, which many of them reach only to die, whilst, on the contrary, thousands of the native inhabitants of Liverpool by their adventurous spirit in almost every part of the world, not unfrequently contract diseases from which, in all probability, they would have escaped in their native air, are still anxious to return to their own land, and have their remains deposited along with those of their forefathers, all of which tend to increase the rate of mortality beyond what would be its legitimate line if dependent only on its own risks, as to employment and locality. Nor is this all. The casualties of a sea-port of such magnitude and bustle are infinitely greater, *which* are neither subject to the situation, nor effect on the constitution by employment. And lastly, Liverpool is the almost only available place of resort (sea air, for bathing, &c.) for one of the most extensive, and certainly most populous manufacturing districts in the world (*not for the rich who*

sire places of resort) but to innumerable shoals of the worn down, emaciated artizans for thirty or forty miles around, thousands in ill-health seek temporary relief, very many in the last stages of phthisis go there because their neighbours go, and others from bad advice, swell the bills of mortality in a distant locality after contracting the cause of death in their own neighbourhood. To be convinced of this the reader has only to perambulate the grave-yards of that extensive sea-port town, when he will find scarcely a tombstone but its records are chiefly those of strangers. After this let the right horse be saddled. Liverpool has in truth been but the last resting place of thousands who have fled thither in hopes of defeating the tyrant hand of death, whose grasp had been felt *as merciless* before they sought a purer air elsewhere.

I must not, however, omit in this place to state that although the manufacturing employment is decidedly and unquestionably pernicious, (indeed I believe the medical man is not to be found who could on reflection deny it,) yet it is equally evident, bad is made much worse by bad habits and indulgencies, producing as a natural consequence miserable dwellings, wretched clothing, and scanty, cheap, and indigestible food.

I shall now bring these introductory remarks to a conclusion, by at once entering on the subject already spoken of. In doing so, without considering which epoch of life is the most important, I shall commence with the period of infancy, and conclude with that connected with the declining years of life.

It is almost unnecessary to request the reader to bear in mind that my subsequent observations are in reference to the working classes only, of a particular occupation, and as such are to be estimated.

CHAPTER I.

From Birth to the Completion of the Second Year.

One of the first objects which arrested my attention (connected with this subject) was the average smallness of the children at birth, not merely in weight but stature. I had been for some time accustomed (as a student in Edinburgh) to see the children of the working classes at birth of much larger average size, and when I commenced general practice in the factory districts in 1822, the contrast appeared to me the more remarkable. From a number of observations I made in the early years of my practice, I found the average weight to be barely six and a half pounds for single births, and about ten pounds for twin cases. In Edinburgh some statements were made of averages at 7½lbs. single births and 11lbs. for twin cases. In respect to the length of the fœtus, authors very generally consider the average length to be about eighteen inches, whilst I was seldom able to meet with a child *that length*, so that the average must be much less. Again, the chalk coloured substance, so frequently found adhering to the child's body, and which is generally associated with fœtuses of meagre growth, is more frequently met with among these districts than in other places; the same may be said of the funis, when very thick. I have often observed a very thin strongly organised funis, attendant on the largest and most healthy children; but in the class of persons alluded to, the thick funis is very prevalent. From these observations, the inference will be drawn *from the size of children at birth*, difficult labours are comparatively rare, *such is the fact*; and on which I shall speak particularly, when on the section of adult female diseases, &c.; but it is necessary to state, that children do not often suffer much from long continued pelvic pressure, although asphixia at birth is a prevalent appearance. In treating of the diseases of early infancy, asphixia will be the first to which I shall direct the attention of the reader. The most usual cause of this affection appears to me to be constitutional debility, they are cases (which with very few exceptions) recover very well by allowing a little time before the funis is divided. I am convinced that many cases prove fatal from the inconsiderate haste often practised in this respect: it ought therefore to be made an imperative rule, never to divide the funis whilst the slightest pulsation remains in the cord. The extent to which apthæ prevails is very remarkable, scarcely a child but what suffers severely from it; and this, in a great measure, is owing to the absurd custom of almost burying the child under the bed-clothing, where the air soon becomes charged with deleterious principles, which the child cannot breathe without considerable injury, which is first manifested on the lining membrane of the mouth and fauces, soon to spread, if not checked, along the whole alimentary canal. Many of these cases, though apparently simple, are remarkably obstinate of cure; and I have found that medical applications are next to useless, if not seconded by improved principles in nursing. No plan succeeds so well as the insisting on the child being so laid as to insure a good supply of fresh air to the lungs; that is, not to bury it in the bed, but place the body so as to be perfectly warm, but the head to be raised on the pillow, and the face bare. It must also be borne in mind, that it is much healthier for the child to lie on a pallet by itself than in company with other children, or even with the parents. The mother, after suckling, should invariably put the child from her, on a separate pallet, by these simple means the first passages will seldom suffer from apthæ. The old remedy of the sodæ boracis rubbed down in honey, is, after all, excellent; the only improvement I can suggest, is the addition of a little pulveris cinchonæ, or a little infusi calumbæ to the old remedy, which makes it considerably more efficacious, and seldom fails in curing, if the above hints in the nursing department be attended to. Acidities in the stomach and intestinal canal are abundant enough in all classes of society; but particularly so among the factory community; arising from the wretchedly-bad nursing, and worse food, to which the children are exposed. I have frequently known mothers compelled to go to factory, and leave their infants (whilst very young) to the care of some hired old woman, who has probably two or three to look after, of different ages—who fed them all with some badly-made, and often sour, porridge, all out of the same vessel,—crammed the children, head and heels together, on a dirty bed, or crib, in a dark corner, as far removed from air as it is from light.

To be Continued.

COURSE OF LECTURES ON THE DIAGNOSIS, PATHOLOGY AND TREATMENT OF DISEASES OF THE NERVOUS SYSTEM,

By MARSHALL HALL, M.D., F.R.S., L. & E. [illegible]

LECTURE II.—Delivered December [illegible], 184[illegible].

GENTLEMEN, I purpose in the present lecture to draw your attention for a very few moments to what passed on the former occasion, and then to shew you the more immediate application to practice of the principles I then laid down; to shew you the practice, as well as the diagnosis and prognosis of diseases.

I take it for granted, now, that we already understand that the nervous system is divided into three portions,—the cerebral, the *true spinal*, and the ganglionic. With regard to the cerebral, I need hardly tell you that it is the system to which we refer all sensations, the senses; we refer to this system also all intellectual and mental operations—the judgment, the memory, and all the voluntary motions. I will just now state to you what I think is a very interesting point arising from this simple arrangement of the subject. Suppose you are called to a case of disease; your object is invariably to ascertain what are the symptoms of the case, and you must go through every one of the symptoms. Now, suppose it is an affection of the brain, where you want nothing to be interrupted, but every symptom to be united, and nothing imperfect what do you therefore inquire for? Whether, in the first place, there be any affection of the senses; whether, in the second place, there be any affection of the intellect; and whether, in the third place, there be any affection of the voluntary motions. You will consider whether there be any affection of the sight, or any affection of the sense of smell, or any affection of the sense of hearing, and so on. These, you will find, will be useful guides to the symptoms of diseases of the cerebral system. Now, then, the next question is, whether there is any affection of the cerebral system? In determining this question, the principle I have laid down enables me to enumerate the functions of the true spinal system. What are those functions? They are, in one word, all the acts of inglutition and deglutition belonging to the animal economy. First of all, the inglutition of the atmospheric air, inspiration, and expiration, in general terms; then there is the ingestion of the food, which is an act of deglutition, or any other function of inglutition there might be; for instance, the act of conception. Then come the acts of expulsion: the expulsion of the fæces, and the function of the bladder—the function of the sphincters. For I have said that the spinal system comprises the orifices and the outlets of the body. What we next come to inquire is, whether there be any morbid affection of the orifices or the outlets. But, to return to the cerebral system. You remember what I stated in the previous lecture. It was, that the cerebrum itself is not capable of exciting motion; that if you injure the cerebrum in any way, or lacerate it in every possible way you can devise, you cannot induce anything like motion or muscular contraction, or spasmodic action. Therefore, it is quite plain that if there be a disease of the brain—confined to the brain—you will have no spasmodic action; you may have an affection of the senses and the intellect—as in insanity; you may have a morbid affection of the voluntary motions, such as the act of mania, but you will not have a spasmodic action. Why will you have no spasmodic action? Because any disease of the brain is incapable of producing spasmodic action, or any muscular contraction. When, if you come to a case of disease of the brain, you find spasmodic action, and at the same time convulsion or contraction, or anything of that sort, you may be sure of one thing,—that, however much of disease of the brain there may be, there must be something more; the spinal marrow itself must be affected. And so with regard to all those functions and motions belonging to the spinal marrow. Now how are we to come at the disease? Suppose a person taken comatose, as in apoplexy. If the disease be limited to the brain, you will have no affection whatever of those functions which belong to the spinal marrow. You may have less consciousness, you may have perfect insensibility, and not the slightest power to move the hand or the leg; but, if you have other symptoms besides, you may be sure the disease is not one of the brain, or that it is not one, at any rate, confined to the brain.

We have lost a very valuable member of the profession very recently from an attack of apoplexy. I was asked the question respecting the probability of his recovery, and I said what are the symptoms? And it proved that there was stertorious breathing. Anything else?—Yes, there was ***disphagia***. Now you observe that in case of *disphagia* you extend beyond the cerebral system, you come to the spinal system, and I can say from the result of my own experience as a physician, and that of others, that *disphagia* is always an exceedingly fatal symptom. I do not mean to say that no patient will ever recover from *disphagia*, but I do mean to say that the prognosis of *disphagia* is more fatal when there are other symptoms of decided apoplexy. If the patient breathe pretty well, you may be sure that no vital organ is affected. But the moment the breathing is affected, the spinal marrow becomes affected, and you may trace the severity of the disease in the severity of the respiration. If continued, the patient dies, if, on the contrary, it ceases, the patient may recover. What I want to impress on your minds is, that if, in addition to cerebral affection, there be a true spinal affection, so the prognosis becomes infinitely more palpable, and the disease infinitely more difficult of treatment. Have we not, therefore, here a clue to the diagnosis? Have we not also a clue to the prognosis?—and have we not more certainty as to our mode of treatment? I have said that the brain is incapable by any injury or laceration to produce spasmodic action. You cannot

touch the spinal marrow in any way but you produce spasmodic action. If you touch the medulla oblongata, or if it be affected by disease in any way, there is immediate convulsive action, immediate muscular contraction. If you then come to a disease in which spasmodic action occurs, you may be sure that the spinal marrow is injured. Disease I have said affects the spinal marrow, but this may be produced by some organic disease elsewhere. And this, I should state, is an important thing, if there be pressure on the spinal marrow it will produce spasmodic action. There is an interesting case recorded by Mr. Laurence, in which a fœtus was born without a brain. When pressure was applied to the medulla oblongata the body was thrown into convulsions. There is also an interesting case recorded by Dr. Abercrombie, in which there was effusion into the ventricle of the brain to such an extent as to separate the parietal bones, and there was a considerable tumefaction. On touching this there was no convulsion, but the moment he touched the medulla oblongata the child was convulsed. You see then what happens when the spinal marrow is injured by organic disease or external pressure. There is a disease of the brain called hydrocephalus. Now in one case of this disease of the brain there are convulsive actions,—and why? Because it is quite obvious there must be pressure on the medulla oblongata. But in one case of hydrocephalus there was no such symptoms, because the bones of the skull were not united,—means could be adopted to separate them from each other? Now in one case you have no injury to the medulla oblongata, whereas in the second case, *pari passu*, the result may be convulsion or spasmodic action; so that it is quite obvious there cannot be convulsive action from pressure or disease of the medulla oblongata, but some other part of the spinal marrow must be diseased. Now then we will return to the disease called hydrocephalus of the brain.

One of the most important symptoms of this disease of the brain is the rigid contraction of the limbs and the muscles of the body. How do you account for this? I have said that disease of the brain cannot produce spasmodic action. How do you account for this then? This question I put to some medical friends of mine in Paris, and not one of them could afford an explanation of the phenomena. It is obvious from what I have stated to you, that in acute hydrocephalus there is a considerable degree of tumefaction produced, which results in a pressure on the medulla oblongata, and here you have the symptoms accounted for.

I think it must be already perceived by you that this study is one which—whether it be viewed with regard to its philosophy or physiology—is one that has immediate application to practice, which is a point of great importance to you all.

Now, before I go any further—to the department of the science of medicine to which this matter has immediate application—I wish to show you that the phenomena I have been describing are made obvious under various circumstances. This frog is deprived of the cerebrum by an incision just below the occiput and just above the origin of the brachial plexus. It was a perfectly lively frog before the incision was made. If I touch one of the anterior extremities, it is immediately withdrawn: but what I wish you particularly to observe is, if I irritate the other extremity it is not withdrawn. Now the first incision made was to sever the brain from the spinal marrow, therefore there can be no voluntary motion. I have removed the central organ of voluntary motion. If I touch the anterior extremities, it will shew there is a connection with the spinal marrow. By what means?—voluntary nerves? No; for that cannot be, unless they continued uninterrupted to the brain. There is here no continuance, inasmuch as I have separated the brain from the spinal marrow, from which the action of the voluntary nerves is reflected to the muscles. What is the reason then that we have no convulsive effect when I irritate one of the limbs? The reason is this—we have divided the *sciatic* nerve. You know that the spinal marrow is the centre from which springs the *sciatic* nerve, and as this nerve receives an impression, its effect is carried out in a reflex way on the muscle. The reflex action is perfect because of the perfect connection with the spinal marrow. At the former lecture I showed you the experiment of a frog de[illegible] of its brain, and its ganglionic system entirely, but I did not show you the more important experiment arising from it. We may deprive the frog of the brain and ganglionic system entirely, we may divide it entirely, and yet we shall find that—the two anterior extremities being endowed with a like proportion of spinal marrow,—when I irritate one extremity it appears to move, and the other does not. It is one of the most remarkable experiments I could bring before you. You have actually a portion of the animal living by the true spinal system. Here I have a salamander, in which the phenomena are exceedingly interesting, because I have actually divided the spinal marrow in three places. This salamander was alive a short time ago, and notwithstanding that I have divided it into three parts, when I touch the anterior extremities they move, when I touch the posterior extremities they move, and when I touch the last portion of all, the tail, that moves also. Another experiment is exceedingly interesting in another point of view. You may have the several parts of an animal in a state of *tetanus*. This salamander is made tetanic by applying to it a few grains of strichnine, and afterwards dividing it. That portion to which the anterior extremities are attached is tetanic, the posterior extremities are tetanic and the tail itself is tetanic. Having made the animal tetanic before I divided it, the portions themselves remain tetanic, and I show this experiment to prove that some change has been effected to cause tetanus in the spinal marrow itself, and the nerves connected with it. Tetanus must have made the change, because every part of the animal is tetanic. Therefore, it is certain that not merely the spinal marrow, but a congeries of organs, or succession of organs connected with it, have been affected, and it is very possible that the communication of the spinal marrow with the ganglia in the crustaceous animals may be really proved by experiments of this simple kind.

To revert once more to the functions of the spinal marrow. It often has the power, when touched or injured by the least thing in the world, of producing spasmodic action, and I need not tell you again that the same power acts in ingluttition and deglutition, and that the same power acts in closing the orifices into the body and closing the exits, the sphincters and passages that lead out of the body. In all spasmodic action the spinal marrow is effected. I do not say primarily, but secondary only, and this is the case with disease of the brain, where the disease or affection of the brain is not confined to the brain itself, but affects other organs. Disease of the brain may occur in a distinct form, in that sense of the word, in connection with the incident nerves. Suppose a case of some morbid crudities being taken into the stomach: these crudities may affect the pneumogastric nerve, which will carry the effect to the medulla oblongata and the impression may be further reflected. This is the case in many convulsive diseases in children, as well as adults. I may just mention a fact which is very well known to you all; you may irritate the sphincter of the bladder. You know the effect of calculus, which is to produce such a contraction of the sphincter ani as to disable the patient from discharging urine. A patient came to me the other day with this complaint. I begged an efficient surgeon to pass a catheter; that gentleman did so without hesitation, and without knowing my object. What was the consequence? He impinged on the calculus. I knew *that* must be the case; but I thought to make the case doubly sure by having the catheter passed. It was one of those happy hits that we experience in pursuing pathological and physiological investigations.

Now, we know nothing of the ganglionic system, or at least, very little is known of that system. That subject remains to be investigated and developed by those who come after me. The ganglionic system is that power under which all formation, all nutrition, all absorption, and all secretion is performed; therefore, that being affected may affect these different secretions. I believe the ganglionic system is divided into two portions—the external and the internal. Now, what are these intended for? We may suppose the internal ganglionic system is for nutrition and absorption, and that the external ganglionic system is for the same purpose; so that, while there are internal organs requiring nutrition, there are also external organs requiring nutrition; and the same with secretion. I need hardly tell you that perspiration is usually performed by the external organ, and that would lead us to suppose that there are internal ganglia for internal purposes, and that the external ganglia may probably be for external operation of the same kind: and it is so. There is a very interesting experiment by M. Majendie; he gave me an instrument by which he could readily divide the fifth pair of nerves within the cranium, leaving the casserian ganglion in that part detached from the brain. It is quite plain, therefore, that here you have the nerve injured with the ganglia upon it. What is the consequence of this injury? The eye is not nourished. It appear to me, therefore, that if you injure the casserian ganglion, the consequence is, that the eye is not nourished; that this organ is the organ of the nutriment of the eye. I must make one remark: it seemed to him that this experiment was of little worth, for it led to nothing. But, gentlemen, it so happened, a very short time after that a patient in one of the hospitals in Paris lost an eye; the surgeon under whose treatment the patient was placed, happened to know the experiment of Majendie, and he said, "what is this,—disease of the eye?" He did not suspect the injury of the nerves which lead to the globe of the eye. he said, "how am I to treat this case? what do you think is the treatment? you have only to press the eye back." Now, in every instance in which the eye is perfect and uninjured in its structure, whenever you touch the eyelash, the eye closes; so that, if you touch the eyelid and it remains stationary, you may come to a conclusion of this kind—that we have a secondary kind of evidence of the destruction of the fifth pair of nerves on the brain. However, very naturally, the patient died. On examination he found the structure entirely disordered; of course, the fifth pair of nerves totally destroyed. Here you have a very interesting series of facts; first of all the experiments founded on the disease—the disease indicating the experiment—and then the series of nerves performing the office of nutrition to the ocular structures under the influence of the casserian ganglion within the brain. If that is the case with one set of nerves, we may argue that it is so with all ganglia in connection with the nerves proceeding from the spinal column. I cannot go further, because I am not aware of any facts to prove it; but, I say, that if the destruction of one ganglion will produce a certain effect, you may conclude that the destruction of the other ganglia of the same kind will produce a similar effect to the organs with which they are connected.

I have just laid before you my notion on the subject. It is that the internal ganglia with their nerves constituting the ganglionic and sympathetic system, are for the purposes of nutrition, secretion and absorption internally; whereas, the external ganglia are for the purposes of the nutrition of the exterior of the body. Having gone thus far, what I wish to do now is to go once more over the three divisions of the nervous system; namely, the cerebro-spinal, the true spinal, and the ganglionic. I might add a few observations on another subject, namely, the state of the functions generally, in a state of rest, and a state of sinking, or a state of slow dissolution; but I would rather leave that part of the subject for a future opportunity, and pursue the subject in a different direction. I want now to bring before you the true spinal system, and to show what bearing it has on that division of the nervous system which I am laying before you. Suppose the case of a fœtus in the uterus. I need not tell you that no use can be made of the internal senses, if they are kept from any external impression. I might almost have said, there is little or no need for the true spinal system. But there is a need of the true spinal system, and it is of this kind. Without the true spinal system, the eye-lids might be irritated; without a

true spinal system, the liquor amnii must pass into the trachea—but I have no doubt the larynx is well covered in the fœtus, so that it cannot depend on the continual operation of the spinal system—and if the larynx is closed, a drop of water placed in the mouth would pass into the glottis. There are secretions in the bladder; now these secretions might be expelled, if it were not for the safeguard of the true spinal system. One most important point of the uterine nervous system is the ganglia. I need not tell you that all formation goes on—every act of formation—every act of nutrition—every act of secretion, implies the continual agency of the ganglionic system. Now this proves what I have been saying, and here we have one of the most remarkable cases. In the first place, the fœtus is born without a brain, and is perfectly developed. It is quite plain that a fœtus perfectly developed may, nevertheless, be entirely destitute of brain. One case is recorded by Mr. Lawrence. The spinal marrow was perfect from the beginning; so were all the ganglia perfect; the infant was perfectly developed all but the cranium, there being an entire absence of brain. For instance, the fœtus was born with no cerebral life. But Gentlemen, the fœtus lived in this case, for a short time, a true spinal life. It eats, and swallows, and evacuates; the intestines and the bladder perform their functions. I wish here to make one remark. It is, that the brain has nothing apparently to do with the functions of the true spinal marrow and the ganglionic system; yet these functions cannot grow without the brain,—that is to say, no animal can live long without a brain, if I except animals of the very lowest orders. If a fœtus is born brainless, it may live forty-eight hours. I have watched a fœtus in this state to see the whole of the phenomena. But what is its life? Its life is mere breathing: a mere capacity for swallowing. Nothing is more interesting. I was going to say, more awful, than to see a human being deprived of that which is the type of humanity—namely, the brain. We know, then, that such a fœtus cannot live; but such a fœtus may cry; that is to say, it may make peculiar noises, which may be considered crying. Yet we should be perfectly aware that such an event may take place. It may take place under much more painful circumstances. I was told, but the other day of a case, similar to a case given in the Medico-Chirurgical Transactions; it was necessary, from deformity of the mother, to have recourse to the step of cranitomy, and this was performed in the most perfect way. The child was born, and it cried; but it is impossible to say that the child cried, in the ordinary use of the word. You can hardly imagine the state of mental harass and suffering of the practitioner in such an event as this. Why do I mention it? In the first case, because it is an exceedingly interesting subject; and in the second case, to put you on your guard, if you are ever called upon to destroy the brain, be quite sure that you destroy the medulla oblongata. Well then, as I said before, the child may live forty-eight hours; it will never live beyond that period. I have made one remark, which I repeat by another observation, namely, that the animal functions cannot go on permanently independent of the brain. In idiots, life is found to be pretty nearly in proportion to the brain. We find that idiots with small brains generally are short-lived, but if the brain be developed they may attain to the age of puberty, or even long life. We have seen, therefore, that a fœtus may be perfectly found without a brain, and may have the medulla oblongata entire. How do we know that? In the first place, there are many cases on record of a fœtus born without brain, without spinal marrow; without a particle of either of these organs, yet perfectly developed. I have such a fœtus in my museum. The fœtus is perfectly sound; every limb is perfect; every internal organ is perfectly formed; the ganglionic system is perfect, and all the nerves going to the spinal canal perfectly formed; nothing is wanting but the spinal marrow. Here then, we have a most perfect formation, all under the guidance of the ganglionic system. The intra uterine life may be quite perfect, although there be neither brain nor spinal marrow; but what happens the moment the child is born? It cannot breathe: it cannot live an instant; that is to say, not longer than it could in any other circumstances, deprived of respiration. Here you have a most interesting fact whilst in that of intra uterine life being perfect during the period of nine months, and the extra uterine life cannot last five minutes.

I must conclude this lecture with an observation or two on circumstances that will occur to you all in actual practice. It often happens that a fœtus is born *still*, apparently in a state of apoplexy. I believe still-born children are, generally speaking, placed in peculiar circumstances. The brain may be compressed, as in hydrocephalus, and that may cause a compression of the medulla oblongata. If that is so the child cannot live; you have no means of removing the cause. But the child may be still-born sometimes, that is to say, it may not begin to breathe, though there is no apoplexy of any kind. Then the first question is as to the diagnosis. I have not the slightest idea of the diagnostic phenomena. One of the most interesting points to determine is the diagnosis between a still-born child in consequence of the compression of the brain and the medulla oblongata, and the other case of asphyxia, depending on other causes. The first question to be considered is,—as respiration is the new life to the fœtus, what is the cause of respiration? I consider Professor Muller perfectly wrong in supposing that the causes of respiration are dependent upon the circulation of the medulla oblongata. I tell you once for all that this perfect circulation of the medulla oblongata is necessary to respiration, and that without this excitor, respiration cannot be excited. However, the respiratory phenomena are not physiological acts, and to this point I shall have again to advert. When the fœtus is born, I believe the first excitement to respiration is the impression of cold air on the nerves of the whole surface. A friend of mine once attending a very interesting case; the child was just born, he waited until he should hear the child either breathe or cry, and having waited for the usual length of time, the child did not either breathe or cry. He was about to take it from under the bed clothes and try resuscitation, when the moment the clothes were lifted up, that moment the child made a gasp. This was the beginning of that respiration, without which life cannot exist. Here is an interesting fact. Suppose a case of an infant still-born, what would you do? You will naturally say what is the physiology of the case? What does nature do? Nature makes an impression on the whole surface—then you may follow nature. I believe it is common to blow in the face of the child, and on the general surface, and in this manner the act of inspiration is excited; if that does not do, then, without allowing the infant to cool—for if it does the impression cannot be made—take a few drops of very cold water, and dash them on the face. There are other means to be adopted, but this I believe to be nature's means, and the imitation of nature's means I think decidedly the best. The surface of the child ought not to be allowed to cool, for if you dash cold water on a cold surface, you will produce no impression; there is no difference of temperature, and therefore no impression can be made. You must take care that the general surface is kept exceedingly warm, and then you produce only a contrast between the warm surface of the body and the cold water. By applying cold water to a surface never cold before, you produce the peculiar effect which is the act of respiration. I will not go further into this subject, because my object is at this moment only just to bring forward facts to illustrate the general subject, and I shall, therefore, leave it for those whose more immediate duty it is to address you on the subject of resuscitation from asphyxia.

I shall now lead you back once more to the subject of the nervous system, especially the true spinal system. I repeat then that the brain is the centre of the cerebral system, and the centre of all those phenomena which relate to sensation, intellectual power, and voluntary motion, and that by means of the brain we are, as it were, connected with the external world mentally. That it is by this means I can place my finger in a certain position, and take up an instrument, or anything else, and put it down again. I make use mentally of external objects—all those objects that are external to my senses. If we want to arrive at an object it is under the guidance of a certain set of nerves that we are enabled to do so; it is by means of the impression made on the external nerves, which impression is reflected on the nerves in the interior of the body. If a certain element or fluid be placed within the larynx, it is often that no sensation takes place, and it shews that it is entirely independent of the cerebral system, because a fœtus without a brain may swallow and perform the organic functions in the same manner as a perfect being.

In the diagram here given

TABLE OF THE TRUE SPINAL AND EXCITO MOTOR SYSTEM.

A. INCIDENT EXCITOR BRANCHES.

—

1. The Trifacial arising from
   - A. The Eyelashes
   - B. The Ala Nasi
   - C. The Nostril
   - D. The Fauces
   - E. The Face.
2. The Pneumogastric, from
   - A. The Pharynx
   - B. The Larynx
   - C. The Bronchia
   - D. The Cardia—kidney and liver
3. The Posterior Spinal, arising from
   - A. The general surface
   - B. The glans penis—vel clitoides
   - C. The Anus
   - D. The Cervix vesicæ
   - E. The Cervix uteri

B. THE TRUE MEDULLA OBLONGATA, THE MEDULLA SPINALIS,—THE CENTRE OF THE SYSTEM.

C. THE REFLEX MOTOR BRANCHES.

—

4.
   - A. The Trochlearis } oculi
   - B. The Abducens } oculi
   - C. The minor portion of the 5th
   - D. The Facial distributed to
     - A. The orbicularis
     - B. The levator Ala nasi
5. The Pneumogastric, or its accessary
   - A. The Pharyngeal
   - B. The Laryngeal
   - C. The Bronchial
   - D. The Cervical, &c.
6. The Hyo-Glossal
7. The Spinal, distributed to
   - A. The diaphragm, and to
   - B. The Intercostal, and
   - C. The abdominal muscles
8. The Sacral, distributed to
   - A. The Sphincters
   - B. The expulsors, the ejaculators, the fallopian tubes, the uterus, &c.

you see the whole of the functions that come under the guidance of the spinal marrow arranged, and it is important to carry that arrangement in your minds, because, whenever you have to inquire into the nature of a disease relating to the spinal marrow, you cannot have a better arrangement in your mind to assist you in ascertaining the different phenomena, and the different symptoms of the disease. If you come to the ganglionic system, you will consider whether it has any relation to the subject; whether any disease can be referred to this system. But I say, the phenomena of this system are very obscure, and so is its morbid anatomy very obscure, and therefore I cannot say one-tenth part about the ganglionic system that I can about the cerebral and the true spinal. There is no question that morbid states of the urine may be induced by morbid states of the ganglionic system, and so also the morbid secretion. In this manner you observe that physiology has immediate reference to pathology; pathology refers to diagnosis, to prognosis, and to practice. Whenever I go to visit a patient who is affected with nervous disease, I always go through in my own mind this arrangement, whether there is any affection of the intellectual power; whether there is any morbid aberration of the mind, or any affection of the voluntary motions. If I see anything established, I trace in my own mind all that relates to the true spinal marrow. I have no difficulty, because I am led to consider which functions are essential to the circulation of the spinal marrow. I also inquire whether there is any internal disease in conjunction with or dependent on any mor-

bid state of the ganglionic system. In this manner I have a most useful pneumonic. I hope I have said enough to convince you that to be good physicians you must be good physiologists. I cannot imagine, that any one can be a good practitioner, without being able to trace in his own mind, all that is known of the physiological condition, as well as the pathological condition of the patient. In fact, without physiology you cannot understand the nature of the disease, or take one step with regard to the treatment. I purposely avoided to day, many allusions to therapeutics, of which I gave you some examples at the last lecture, and I am anxious not to protract the subject beyond the second lecture; especially because I think that the ensuing lectures ought to be confined to the diseases of the nervous system. I shall therefore take up, at the next lecture, the cerebral diseases, and then go in the usual manner to the different diseases of the nervous system.

THE MEDICAL TIMES.

SATURDAY, DECEMBER 24, 1842.

A false-hearted rogue, a most unjust knave; I will no more trust him when he leers, than I will a serpent when he hisses: he will spend his mouth, and promise like Brabler, the hound; but when he *performs*, astronomers foretell it: it is prodigious; there will come some change.

SHAKSPEARE.

WHAT, in the name of charity, are we to do with that miniature Paracelsus of the Nervous System—Dr. Marshall Hall? What unseen demon possesses him, that he so resolutely violates all that common sense and honesty most plainly teach in his eagerness, to make enemies, and hasten his ruin? Horse-whipped by a few—snubbed and disowned by many—laden, bowed down, shrivelled up with the contempt and hatred of more; shunned and detested as something loathsome in the pathways of Science, by all who at any time have been condemned by circumstances to put up with his acquaintance—thus discredited,—thus dishonoured,—thus degraded—without a friend—without scarcely a recognizing acquaintance, he yet acts—this wretched man—as if he had no future duties on this earth but to prove the justice of his ignominies, the personal earning of his calamities. Where, or under what circumstances, is it possible to conceive so favourable a fortune for him, as in the forbearance, the kindness, the overflowing charity with which we have ever treated this unfortunate victim of his own unprincipled temper? When referring, a short time back, to the unmerciful pecking he received from Dr. Copland, who pulled from him—before the amused audience of the Medical Society—every gaudy feather with which, at Sprengel's and Boerhaave's expence, he had so liberally decked himself—did we not step out of our way to urge him to more original efforts, on the friendly plea, that he might trust more to the native powers of his own mind? At various intervals, have we not inserted the little notices to which he was personally anxious to attract public attention?—charitably feeling that, if true, but not new—or new, but not true—'twas a pitiful category, which should not hinder our recollecting that, as the plainest wife must have clothing, and the poorest horse stabling, a persecuted physician can pay for neither, without patients. Finally, a fortnight since—summing up our kindness in one cumulated effort—did we not pledge ourselves to do him that service of services—the "sorest test" of friendship—*publish his lectures?* And, stretching courtesy to its height—using that liberty with our own friends, we would not have ventured on to the readers of any other Journal—did we not speak of these lectures as a suitable pendant to our admirable lectures by Professor Owen (perhaps the similarity of *subjects* may pardon this), and further, venture to attach to his name (in *our* own Journal, at least) that word, "*distinguished*," which, applied to any other F.R.S., would have carried not the most distant shadow of irony with it, but which, applied to our unfortunate Paracelsus, has produced us more quizzing letters than all the other subjects ever handled in the *Medical Times?* Was ever godsend, to a man struggling with circumstances, more complete or perfect than this? But our predestinated friend returns for this—the aid, the kindness, of a powerful Journal—not "*une isolation noble et fiere*," though that might be absurd enough, but a bold course of desperate hostilities, which he even violates honour and breaks faith, forthwith to commence. It is written, that the hand of Ishmael was against every man, and every's man's hand against him. Verily, Marshall Hall, reviving this worthy character, is our MEDICAL ISHMAEL. Appropriating, as usual, his predecessor's highest feats in this peculiar mode of distinction, he (not as usual) here excels him—for our Ishmael's hand is not only against every one else, but against himself,—his hand is against *Hall*, and the hand of *Hall* against him. But, without more preface, let us put the whole transaction before our readers,—such as Dr. Ishmael Hall's letters to the Editors of the *Medical Gazette* and *Lancet*, with our explanatory reply, exhibit it. Our reply has been sent to the Editors of those two Journals,—and as we cannot, with stretched ingenuity, divine a reason why it can *honestly*, or even decently, be denied by them publication, we may take it for granted that it will appear, at least, in the *Medical Gazette*. To the conductors of the *Lancet*, "honesty and decency" are appeals that find no place to impinge on.

To the Editor of the Medical Gazette.

SIR,—Observing an advertisement on the cover of the last number of your journal, relative to the publication of my lectures, I think it proper to make the following statement.

The short-hand writer of the *Medical Times* called upon me a few days before the commencement of my lectures at St. Thomas's, to say that it was his "*intention*" to take down my lectures for that publication, adding that, as he was not versed in medical terms, it would be a service to *him* if I would correct any verbal errors in his MS. I replied that I had no objection to do so; preferring that my lectures, if published at all, should be published correctly. When I read over the notes of the first lecture, I found them, from the cause assigned, so incorrect, that it became necessary to re-write them. This too, from the same motive, I was also ready to do, time being given. But having consented to correct my lectures for correctness' sake, I did not expect that *the matter would be made public, as if I had entered into a spontaneous arrangement* with the editor of that publication. I beg to add that, on seeing the advertisement on the cover of your journal, I immediately addressed that gentleman, withdrawing any co-operation whatever in this matter.

I am, Sir,
Your obedient servant,
MARSHALL HALL.

Manchester Square, Dec. 10, 1842.

(REPLY.)

To the Editor of the Medical Gazette.

SIR,—Your insertion of Dr. Marshall Hall's *injurious* and certainly *not over correct* charges, gives me a claim, in *honest English fair play*, to a reply; and I dare say our being fellow Journalists will not invalidate that claim.

As far as Dr. Hall has made himself understood to me, his charge or charges resolve themselves into this:—That I announced his correction of his lectures "*as if* he had entered into a spontaneous arrangement with me." He does not complain of my doing something, but my doing it as "*as if*"—a kind of constructive guilt which once counted against the sovereign, and still counts, it seems, against Dr. Marshall Hall, Fellow of the College of Physicians. Unfortunately, even this ingenious "constructive" charge is without truth. The announcement I ordered is the shortest, plainest, least ambiguous, and most free from "*as ifs*" possible, viz., "a set *reported verbatim expressly* for the MEDICAL TIMES, and carefully corrected by the Lecturer"—calling the most possible attention to the reporter's labours or merits, and the least possible to those of Dr. Hall. When Dr. Hall therefore asserts that I announced explicitly or implicitly "his entering into a spontaneous arrangement with me," he says that which is not true, as he knew. But though I announced no such thing, Dr. Hall *knows there was a spontaneous arrangement*—with *me* too—and not with me only,—but with the *reporter* also; and this twofold spontaneous arrangement was not only to *correct*, but to RE-WRITE his lectures: and conscious of this disgraceful compact—for it was disgraceful to *him*, if it were meant underhand and on the sly; his timidity took everything, however distant, for the divulgement of his *compromising* secret. He himself avows he did not discourage the reporter's intention to give his lectures. *He* owns he offered him assistance; that he pledged himself to *correct*, nay to rewrite them, and although he now explains the latter offer by the flimsy and palpably false pretext, that the lectures needed it from the incorrectness of some *medical terms* (which any medical man could correct in five minutes) yet the fact is unchanged, that he did enter into a spon-

taneous arrangement *with the reporter*, first to have his lectures reported, secondly, to revise them when reported, and thirdly, *to rewrite* them. But further, though Dr. Hall says he undertook the revision and rewriting to do a personal service to the reporter, who applied, according to Dr. H., not for me, not for the journal, but for *him*, the reporter, (Dr. Hall marks this fact in italics) yet unwritten to by me, unasked, uninvited, spontaneously, if he like the word better, did Dr. Hall *write* to me, hitherto a passive party in this matter—to what effect do you think. Sir? Why, that it had *occurred* to him (kind friend!) that it might be well to postpone the insertion of his lectures until the first number in the new year," and "*undertaking* in that event to write them out himself." He gave his reasons. "They would be *more* perfect, *and of more service to me*." (the editor of the M.T.) But his considerate kindness, his provident solicitude for me did not end here, for he "arranges" to do the work "well," and concludes with a familiarity of friendship which puts my modesty to confusion. "YOU MIGHT INSERT SEVERAL NOTICES, AND EXCITE A LITTLE EXPECTATION!" This letter is dated the 8th inst., the advertisements announcing careful revision by the lecturer appeared on the 10th. So you see, sir, the "spontaneous arrangement" which the fastidiously delicate "Fellow" thinks so disgraceful even in imagined possibility, absolutely did take place in full plenitude, with every aggravating complication, and that too not only with me, but with my *employé* also!

Dr. Hall being a gentlemen who can do great good on small inducements, says that he offered to re-write the lectures because they were so faulty. They may be faulty—but as every one sees on reading them, they are exactly as he delivered them. If this then be a charge against himself, let him answer it to his insulted audience—if against the able reporter, whose bread depends on his reputation, it is a miserable calumny which no man of spirit, however driven in self-defence, would have resorted to.

That reporter's answer to this, as to Dr. Hall's other statements, is conclusive. He affirms that, directly or indirectly, Dr. H. *sought* the report of his lectures in the MEDICAL TIMES, unasked, gave him a card to the lectures, invited, courted, welcomed the revision of the lectures—declared, when he saw the first, that it was "word for word," and read it *before the reporter* in his own parlour saying page after page "there is nothing to correct in that;" and he further asseverates, that Dr. Hall at every interview was exuberant in his expressions of anxiety to serve the editor of the MEDICAL TIMES, and felicitated himself that he had now an opportunity of making what he called "an atonement for his past inactivity." If Dr. Hall, therefore, be not —as universal report has it—fatally compromised to the *Lancet* by the reviewship of his own books, none but himself can understand or explain the excito-motor principle of his recent letter to you—a letter which, whatever may be thought of the originality of his physiological theories, puts that of his civic practices far, very far, beyond dispute.

Replies, sir, always require more space than charges, which are often mischevious in proportion to their unspecific brevity; but I trust you will overlook the length to which my observations have extended in pity for an unfortunate brother editor involved *bongré, malgré* in a contention with a person in whom the very genius of professional squabbles seems to be incarnate—who, as if under some singular fatality, can have no dealings either with his contemporaries or predecessors in medical science save to their loss. Appending to this statement, the explanatory observations of my much esteemed collaborateur, Mr. Piers Healey, the barrister, and of Mr. Gregory, the reporter engaged in the case,

I am, Sir,
Your obedient Servant,
The Editor of the "Medical Times."

Note from Mr. Healey.

My Dear ——,

I am too happy to have an opportunity of expressing my entire concurrence, not only in your statement of facts, but in every sentiment you have expressed in reference to them. If Dr. Hall, after your *exposé*, which I now very willingly make my own, do not lose caste —if that misfortune still await him—I shall have an humbler opinion of the heads of your noble profession, than anything in their past history warrants.

Believe me, my dear ——,
Very faithfully yours,
T. PIERS HEALEY.

Essex Street, Dec. 17th.

Reporter's Note.

16, St. James's-st., Clerkenwell.

Sir,—Having read your note to the editor of the *Medical Gazette*, I conscientiously testify that all therein related, with regard to myself and my interviews with Dr. Hall, is true to the letter. And, in contradiction to Dr. Hall's statement, which to my own knowledge contains but one assertion which is not either a falsity or a mutilated truth, I pledge my character as a short-hand-writer of nine years' experience to the entire correctness of my reports of the lectures, now in course of publication in the MEDICAL TIMES.

I am, Sir,
Your obedient Servant,
H. GREGORY.
